1 INTRODUCTION

1.1 Background and Scope

All radicals contain one or more unpaired electrons (UPEs), each with its own magnetic dipole moment arising from its spin. Radicals are therefore paramagnetic and possess net spin moments that can interact with the magnetic component ($\mathbf{B}_1$) of incident electromagnetic radiation. This interaction gives rise to electron paramagnetic resonance (EPR) spectra, one of the most versatile and useful techniques for studying radicals. There is a close analogy between EPR (also called *ESR*, *EMR*) and the more familiar nuclear magnetic resonance (NMR) spectra. This article focuses on the isotropic spectra obtained from organic mono radicals and radical ions in solution. Numerous textbooks and monographs are available covering anisotropic spectra, electron nuclear double resonance (ENDOR) spectra, pulsed EPR techniques, and related topics.^{1–4}

Paramagnetic resonance absorption was first observed on a $\text{CuCl}_2 \cdot 2\text{H}_2\text{O}$ sample by Zavoiskii using radio frequency irradiation and a low field.⁵ Continuous wave (CW) EPR instruments operating in the microwave region at about 9 GHz with magnetic fields of about 300 mT (X-band) were the workhorses of the technique until around the start of the twenty-first century. Since then high field/high frequency spectrometers, pulsed spin-excitation spectrometers, double resonance instruments, and so on have become commercially available and are enabling EPR to expand into new

areas of biology and materials science. Extensive and valuable tables of EPR data, particularly for organic radicals at X-band, have been published in the Landolt–Börnstein series.⁶

1.2 Basis of the EPR Technique

In a CW EPR experiment, the paramagnetic sample is placed in a static magnetic field $\mathbf{B}_0$ where it is irradiated with electromagnetic radiation of frequency ν having oscillating magnetic component $\mathbf{B}_1$. The static magnetic field is scanned and the electron undergoes transitions between available energy levels. These transitions occur when the energy of the incident photons ($h\nu$) matches the separation of the energy levels (ΔE).

$$\Delta E = h\nu \quad (1)$$

At each transition, power is absorbed from the incident microwave radiation and this is detected and amplified. The EPR spectrum is usually a display of the first derivative of this absorption as a function of the applied magnetic field.

The energies of the electron and nuclear dipoles in the radical are proportional to the strength of the static field and also depend on their orientations with respect to it. Radicals of small to moderate size undergo random Brownian motion in fluid solvents and this usually averages the anisotropies of the Zeeman and hyperfine couplings to zero. Under these conditions, and taking the static magnetic field to be in the z -direction, the energies can be obtained

from the spin Hamiltonian $\hat{H}$ given to first order by (2)^{7–9}:

$$\hat{H} = g\beta_e \mathbf{B}S_z + \sum a_i I_{z,i} S \quad (2)$$

The first term in (2) represents the electron Zeeman interaction and contains the dimensionless spectroscopic splitting g -factor, β_e , the *Bohr magneton* (a constant equal to $eh/4\pi m_e c$), $\mathbf{B}$ the vector of the magnetic field, and S_z , the spin angular momentum operator of the UPE in the z -direction. The constants a_i are the isotropic hfs constants that quantify the isotropic interaction of the electron with each magnetic nucleus. They can be positive or negative but only the magnitudes are directly accessible from EPR measurements (the signs can be determined by NMR). The spin operators, S_z and I_z , act on the spin wave functions to yield eigenvalues $m_s = \pm 1/2$ and $m_I = -I, -I+1, \dots, I$ for the electron and nuclear components, respectively. The available energy levels are given by (3):

$$E_{\text{iso}} = g\beta_e B m_s + m_s \sum a_i m_{I,i} \quad (3)$$

where B is the field at resonance. The resonance lines appear in the EPR spectrum at the following fields:

$$B = \mathbf{B}_0 - \sum a_i m_{I,i} \quad (4)$$

In the case of a radical containing no magnetic nuclei, (3) yields $E_{\text{iso}} = g\beta_e B m_s$. Radiation induces transitions, that is, changes in the orientation of the electron spin relative to B_z , between the lower and the upper energy levels. Since $m_s = -1/2$ and $+1/2$ for the lower and the upper levels, respectively, ΔE becomes $g\beta_e B$ and hence the condition for an EPR transition is as follows:

$$\Delta E = h\nu = g\beta_e B \quad (5)$$

Consider a radical containing two $I = 1/2$ nuclei coupled to the UPE with hfs a_1 and a_2 ($a_1 > a_2$). Equation (4) indicates there will be four resonance fields at $B_1 = \mathbf{B}_0 - 1/2 a_1$, $B_2 = \mathbf{B}_0 - 1/2 a_2$, $B_3 = \mathbf{B}_0 + 1/2 a_2$, and $B_4 = \mathbf{B}_0 + 1/2 a_1$. The allowed EPR transitions are those in which m_s alters by ± 1 , while the nuclear spins stay unchanged ($\Delta m_I = 0$). The spectrum will consist of four lines separated by a_1 and a_2 as shown in Figure 1. Since each nuclear

Figure 1 Energy levels and transitions for a mono-radical containing two spin $1/2$ nuclei. The corresponding EPR spectrum is below the field axis.

spin state is equally probable, the four lines are of equal intensity.

For radicals with groups of two, three, four, and so on of equivalent nuclei, the corresponding spectra are triplets, quartets, quintets, and so on with intensities according to the coefficients of the binomial series. For radicals with several nonequivalent sets of nuclei and with nuclei having $I > 1/2$, the EPR spectra can be extremely complex; such spectra are often incompletely resolved and analyzing them is a nontrivial task. Second-order spectra, sometimes containing additional lines, are obtained for radicals with relatively large values of a_i .¹⁰

1.3 Relaxation Phenomena and Line Shapes

When electromagnetic radiation interacts with an assemblage of free radicals in a magnetic field, there is an equal probability of spin flip from the upper or the lower level. For net absorption of radiation, giving an observable EPR spectrum, it is necessary for there to be more electrons in the lower state. The ratio of the number of spins in the lower level

(N_L) to the number of spins in the upper level (N_U) is determined by the Boltzmann distribution:

$$\frac{N_U}{N_L} = \exp\left(\frac{-\Delta E}{kT}\right) = \exp\left(\frac{-g\beta_e B}{kT}\right) \quad (6)$$

As long as the assemblage of radicals remains in thermal equilibrium, N_L will exceed N_U and net absorption will ensue. Although the energy gap at X-band $g\beta_e B$ is small in comparison with the average thermal energy kT , sophisticated instrumentation ensures that EPR is a very sensitive technique. In solution, radical concentrations of 10^{-8} M can routinely be detected and, under favorable circumstances (simple spectra, low temperatures) nanomolar concentrations can be studied.

When a sample of radicals absorbs radiation, the number in the upper level will increase until $N_U = N_L$, or even $N_U > N_L$, for large energy pulses. When $N_U = N_L$, there will be zero net absorption of microwave radiation and the EPR spectrum will shrink to zero. In this situation, the spectrum is said to be “saturated” and this occurs for most radicals at high enough power of the incident microwave radiation. There exist mechanisms whereby the electrons in the upper level lose energy to the surrounding medium, or internally, such that they return or “relax” to the lower level. The loss of excess energy to the surroundings takes place by an exponential decay, which is characterized by the spin–lattice relaxation time τ_1 . The spin–lattice relaxation time is related to the mean lifetime of a given spin state and so has an effect on the linewidth.

According to the Heisenberg uncertainty principle, the “width” or energy range δE of a short-lived excited state is not well defined but is related to its lifetime τ by $\tau\delta E = h/2\pi$. A certain broadening will be observed in the resonance transition and, on substitution from Plank’s equation, the following relationships are obtained:

$$\Delta\nu \approx \frac{1}{\tau} \quad \text{or} \quad \Delta B \approx \frac{h}{g\beta_e \tau} \quad (7)$$

This kind of line broadening is called *lifetime broadening* and defines the *minimum* linewidth for a given system. Spin–lattice interactions are particularly important for radicals in condensed phases where the spin system can be directly

coupled to the vibrations of the lattice (phonons). In this case, τ in (7) will be dominated by τ_1 .

In fluid solution, the motions of the solvent molecules provide a less efficient thermal sink and a second process known as *spin–spin relaxation* usually plays a more important role. Magnetic interactions between nuclei and electrons, and between like spins, are an extremely efficient means of relaxing both nuclear and electron spins. This dipolar interaction causes *mutual* spin flips so that the lifetime of spins in the upper state is limited, but the total number of spins in the state remains the same. It follows that this spin–spin relaxation, with relaxation time τ_2 , contributes to the lifetime broadening of the resonance line but does not affect the level of saturation. For free radicals in solution, it is often τ_2 that limits the linewidth; that is, $\Delta B = h/g\beta_e \tau_2$.

Deeper insight into spin relaxation is obtained from solutions to the Bloch equations for the time dependence of the magnetic moment of an ensemble of spins under the conditions of EPR experiments.^{11,12} The Bloch equations furnish expressions for the real (χ') and imaginary (χ'') parts of the magnetic susceptibility of the ensemble of radicals in terms of just the two relaxation times τ_1 and τ_2 . The real part χ' relates to the EPR *dispersion spectrum*, which is less useful than the *absorption spectrum* and is rarely recorded. The expression obtained for χ'' relating to the conventional *absorption spectrum* far from saturation is

$$\chi'' = \chi_0 \frac{\tau_2 \omega_0}{1 + \tau_2^2 \gamma_e^2 (B_0 - B)^2} \quad (8)$$

χ_0 is the bulk static magnetic susceptibility, ω_0 is the angular frequency of the microwave radiation at resonance ($\omega = 2\pi\nu$), and $\gamma_e (= -2\pi g\beta_e/h)$ is the magnetogyric ratio of the electron. The power P absorbed per unit sample volume (V) by the ensemble of radicals from the microwave radiation is

$$P = 1 \frac{\omega \chi'' B_1^2}{\mu_0 V} \quad (9)$$

where μ_0 is the magnetic permeability of the vacuum. The expression (8) takes the form of a Lorentzian function and this is the EPR lineshape observed under conditions of slow field sweep and with power levels below saturation. With these conditions, the linewidth at half height ($\Delta B_{1/2}$) is

given by (10):

$$\Delta B_{1/2} = \frac{2}{\gamma_e \tau_2} = 3^{1/2} \Delta B_{pp} \quad (10)$$

Equation (9) shows that the power absorbed by the sample is proportional to χ'' , and therefore to the number of paramagnetic species present. The power absorbed by the whole sample (P_w), during a scan through the whole EPR spectrum, is given by $\int P dB$ which is a measure of the area under the absorption curve. Hence, the number of spins in a sample is proportional to the integral of the absorption curve, or the double integral of the more usually recorded first derivative spectrum.

In a real CW EPR spectrum of a radical in solution, the lines are often Lorentzian or nearly Lorentzian in shape (Figure 2). However, when additional factors come into play such as slight anisotropies due to inefficient tumbling, unresolved hyperfine interactions from substituents or the surrounding liquid, or static dipolar interactions, the lineshapes tend to Gaussian, in which case the linewidths are given by (11):

$$\Delta B_{1/2} = \frac{2(\pi \ln 2)^{1/2}}{\gamma_e \tau_2} = (2 \ln 2)^{1/2} \Delta B_{pp} \quad (11)$$

Figure 2 Gaussian EPR lineshape; (a) absorption curve, (b) first derivative. Analogous Lorentzian lineshapes (c) and (d). Note the difference between $\Delta B_{1/2}$ and the peak to peak linewidth ΔB_{pp} .

2 ISOTROPIC g -FACTORS

The field experienced by an UPE will differ from the static magnetic field $\mathbf{B}$ because of local fields, which may be permanent or may be induced by the external magnetic field. To allow for this, the dimensionless g -factor of (3) is understood to be variable. The effective field can be written as

$$\mathbf{B}_{\text{eff}} = (1 - \sigma)\mathbf{B} = \left(\frac{g}{g_e}\right)\mathbf{B} \quad (12)$$

Here, σ is the analog of the “chemical shift” parameter of NMR spectroscopy and it is replaced by g in EPR spectroscopy. Orbital angular motion of the UPE is an important contributor to the local field. In many transition metal ions, spin–orbit coupling is large so that g deviates greatly from $g_e(2.00232)$. For most organic radicals in solution, on the other hand, the ground state has zero orbital angular momentum and so the isotropic g is close to g_e . However, in the majority of radicals, a small amount of orbital angular momentum from excited states is mixed in causing g -factors to diverge from g_e . The observed g -factors are sensitive to the local environment surrounding the UPE and can be used for radical characterization in much the same way as chemical shifts from NMR spectroscopy.

Experimentally, the g -factor of a radical can be determined from the EPR spectrum by the use of (5). This requires the measurement of the frequency ν and the field B with an accuracy beyond that of most commercial spectrometers. It is normal, therefore, to add a standard of known g -factor (in a capillary tube, or otherwise) to the sample of the unknown radical such that spectra of both the standard and unknown are simultaneously scanned. Symmetrical spectra free from distortions are required for the uncorrected fields at the center of the standard (B_S) and the center of the unknown (B_X) to be read off the spectrum. The unknown g -factor g_X can then be obtained from (13):

$$g_X = g_S - \frac{g_S(B_X - B_S)}{B_S} \quad (13)$$

Standard radicals frequently used include DPPH ($g = 2.00354$ in PhH soln.), perylene ($g = 2.00257$ in conc. H_2SO_4), weak pitch ($g = 2.0028$ in KCl powder), and TEMPONE ($g = 2.0062$ in PhH

Figure 3 Central ranges of isotropic g -factors of organic radicals in solution (data from Ref. 6).

soln.). The central ranges for g -factors of common radical types are presented in Figure 3.

For an unknown radical, the g -factor is a valuable indicator of the principal site of the UPE. The ranges of values (Figure 3) occur because additional functional groups in the vicinity of the UPE affect the spin–orbit coupling. A few radicals such as acyl, diazenyl, and some phosphorus-centered radicals have g -factors $<g_e$. Most C- and Si-centered radicals, and radical ions, have g -factors of about 2.0026, but multiple substituents substantially increase this. Nitrogen-centered radicals including iminyls and aminyls have g -factors in the range 2.003–2.004. Nitroxides (aminoxyls) are the most common type of persistent radical and they have very characteristic g -factors around 2.006. Most aryloxy radicals and semiquinone radical anions have g -factors around 2.0045. Many alkylperoxyls have large g -factors close to 2.015. Extensive tables of isotropic g -factors for many radical types can be found in Ref. 6.

3 INTERPRETATION OF COMPLEX SPECTRA

At X-band, the applied field $\mathbf{B}$ is large compared to almost all hfs, so isotropic spectra show a

symmetrical cluster of resonance lines around the central field B_0 . A set of hfs (a_i ; analogous to j in NMR spectroscopy) quantifies the electron–nuclear interactions. For radicals in which the UPE interacts with only a few sets of nuclei, the spectra can be interpreted and the a_i values determined by simple inspection of the multiplets that appear. The line heights should also be symmetrical, but non-ideality can result from slow tumbling of the radicals. Serious asymmetry usually indicates that spectra from two or more radicals, with different g -factors, are superimposed. Hyperfine splittings are usually expressed in millitesla or Gauss [$a(\text{G}) = 10a(\text{mT})$] but can also be reported in MHz [$a(\text{MHz}) = 1.3996ga(\text{mT})$].

The following rules are helpful in analyzing spectra:

1. The separation between the two outermost lines at high field (or low field) is almost always the smallest hfs. Note, however, that the outermost low intensity lines may be hidden in noise.
2. The spectral extent ΔB_w is the separation between the low and high field outermost lines and for $I = 1/2$ nuclei, it is given by $\Delta B_w = \sum n_i a_i$, where $i = 1, \dots, N$. Here, N is the number of sets of equivalent nuclei and n_i is the number of equivalent nuclei with hfs a_i .

Figure 4 Deduction of hyperfine splittings a_i from an EPR spectrum.

3. A spectrum with a central line indicates the presence of an even number of $I = 1/2$ nuclei. However, the presence of central line does not exclude an odd number of nuclei.

For the model spectrum shown in Figure 4, the two outermost lines form a doublet with separation 0.12 mT and so this is the smallest hfs a_1 . The doublet pattern indicates that this results from interaction with one $I = 1/2$ nucleus. A triplet splitting from two $I = 1/2$ nuclei starts 0.42 mT upfield from the first (a_2). A doublet from one $I = 1/2$ nucleus starts 0.61 mT upfield again (a_3). The measured spectral extent ΔB_w is 3.77 mT. Thus, the final hfs can be found from the difference: $\Delta B_w - [1 \times 0.12 + 2 \times 0.42 + 1 \times 0.61] = 2.20$ mT. Inspection shows that this corresponds to a 1:1:1 triplet with hfs 1.10 mT from an $I = 1$ nucleus (N, a_4). In this species, therefore, the UPE interacts with two nonequivalent H-atoms, a CH_2 group, and an N-atom as expected for the radical anion of 5-ethyl-2-nitrothiophene. Analyses such as this should be confirmed by computer simulation of the spectrum using one of the freely available packages for isotropic spectra. (The WINEPR SimFonia package is freeware available from Bruker Corporation and runs in the MS Windows environment).¹³

Definitive analyses of complex and imperfectly resolved spectra present formidable problems. It

may be possible to deduce one or two of the a_i values using the above rules. The Winsim2002 software, and the MATLAB-based package EasySpin,¹⁴ are particularly useful because they directly read experimental EPR spectra from several different file formats. The simulated spectrum is compared with the experimental spectrum and a correlation coefficient is outputted as a measure of the goodness of fit. Application of the Winsim2002 autocorrelation function to the experimental spectrum provides a list of hyperfine parameters. The list contains all the required a_i values for the unknown radical mixed up with sums and differences of the a_i values. On the basis of this list, a likely set of a_i can often be guessed and the resulting simulation compared with experiment. Help in estimating appropriate a_i values can also be obtained from literature data for model radicals or from *ab initio* computed hfs. By working through several iterations of inputted a_i and comparison of the simulated and experimental spectra, it is often possible to obtain good simulations of even very complex spectra of unknown provenance.

In difficult cases, it is necessary to obtain and compare spectra from a series of radical isotopomers. Deuterium (D , ^2H) has $I = 1$ and since $a(\text{H})/a(\text{D}) = [\mu_{\text{D}}/I_{\text{D}}]/[I_{\text{H}}/\mu_{\text{H}}] = 6.5$ substitution of H by D usually means the hfs from the substituted H-atom is removed (to within the linewidth) or becomes a smaller set of 1:1:1 triplets.¹⁵

A simplified spectrum, which is easier to interpret, often results. Similar simplification can be achieved by substitution of ^{14}N ($I = 1$) by ^{15}N ($I = 1/2$). Occasionally, ^{17}O ($I = 5/2$) has been introduced in place of ^{16}O ($I = 0$) to confirm the site of an O-atom, notably in peroxy radicals.^{16,17}

4 INTERPRETATION OF ISOTROPIC HYPERFINE SPLITTINGS

4.1 The Origin of Hyperfine Splitting

The magnitude of the isotropic interaction depends on the probability of finding the electron at the nucleus. Clearly, this hinges on the character of the orbital containing the UPE. In general, the spins of electrons and nuclei are coupled by the *Fermi contact interaction*, which represents the energy of the nuclear moment in the magnetic field produced at the nucleus by the spinning electron. The Hamiltonian operator corresponding to this is given by (14)

$$\hat{H}_c = \left(\frac{8\pi}{3} \right) g\beta g_n \beta_n \delta(\mathbf{r}) \mathbf{S} \cdot \mathbf{I} \quad (14)$$

The Dirac delta function $\delta(\mathbf{r})$ ensures that this is only effective when the electron has a finite probability of being at the nucleus. Thus, $\hat{H}_c$ only has finite values for s-orbitals because p-, d-, f-, and so on orbitals have zero density at nuclei, and hence only electrons with some s-character can interact with the corresponding nucleus. The hfs derived from (14) takes the form

$$a_n = \left(\frac{8\pi}{3} \right) g\beta g_n \beta_n \rho(r_n) \quad (15)$$

where $\rho(r_n)$ is the *spin density* evaluated over the volume of the nucleus.

In π -type neutral radicals (methyl, allyl, cyclohexadienyl, etc.), aromatic radical ions, and similar species, the UPEs are contained in π -molecular orbitals (MOs) that extend over much of the molecular framework. The π -MOs have a node in the plane of the radical, where many of the H-atoms, ^{13}C , and other magnetic nuclei reside. At first sight, it appears that electron–nuclear coupling should be zero, but in practice exchange forces bring about coupling of the π -electron with σ -electrons in the

Figure 5 Spin polarization in a C–H fragment of a π -radical.

molecular framework. This phenomenon, known as *spin polarization*, can be understood by reference to a C–H fragment forming part of a π -radical. Two arrangements of the spins (a) and (b) are possible (Figure 5). However, because of exchange coupling between the π - and σ -orbitals, arrangement (a) is slightly lower in energy.

In (a), the two spins on the C-atom (α) are parallel, leading to a favorable exchange interaction. Hence, there is a slight excess of α -spin in the σ -orbital and a corresponding excess of β -spin in the H-atom's s-orbital. The α -spin on the π -orbital induces β -spin at the H-atom and hence the spin density at the H-atom is negative, and so is the H-atom hfs to the π -electron. In (a), the α -spin of the π -electron induces α -spin in the σ -orbital centered on the C-atom and hence the hyperfine coupling to the ^{13}C -nucleus ($I = 1/2$) will be positive.

McConnell showed that the hfs $a(\text{H})$ of H-atoms in π -type radicals are directly proportional to the π -electron spin densities ρ_π in the p-orbitals of the C-atoms to which they are attached^{18,19}:

$$a(\text{H}) = Q\rho_\pi \quad (16)$$

The relationship has been tested for many diverse series of π -type radicals and radical ions and reasonable linearity resulted with Q usually in the range -2.2 to -2.9 mT.²⁰ This simple relationship enables a rough picture of the distribution of unpaired spin in a free radical to be built up from the experimental hfs of “reporter” H-atoms.

4.2 Hyperfine Splitting from Nuclei Two or More Bonds from the UPE

The distances of H-atoms from a radical center, which may or may not be part of a π -delocalized

Scheme 1 Conformations of $R_2C^\bullet-CH_2^\beta R'$ radicals.

system, are usually indexed as shown in **1** (Scheme 1).

Thus, H^α are one bond away from the π -orbital containing the UPE, while H^β , H^γ , H^δ , and so on are two, three, four, and so on bonds, respectively, removed from the radical center. For H^β -atoms, interaction with the UPE occurs mainly by a hyperconjugative mechanism. The π -orbital containing the UPE has correct symmetry for direct overlap with the σ -orbital of the $C^\beta-H^\beta$ bond (**2a**, Scheme 1). This mechanism implies that H^β hyperfine splittings should be positive and this has been confirmed by NMR experiments. The direct nature of the overlap in **2a**, **b** leads to sizeable β -hfs, which are often larger than α -hfs. For example, in the ethyl radical, where there is free rotation about the $C^\alpha-C^\beta$ bond, the measured $a(H^\alpha)$ is 2.24 mT, whereas the $a(H^\beta)$ is larger at 2.69 mT.

In nonrigid radicals, a degree of torsion about the $C^\alpha-C^\beta$ bond takes place in solution. The extent of overlap, and hence the magnitude of $a(H^\beta)$, will depend on the dihedral angle θ between the π -orbital and the $C^\beta-H^\beta$ bond (**2b**). This angle varies with the rate of internal rotation about the $C^\alpha-C^\beta$ bond, which depends on temperature. It follows that $a(H^\beta)$ are also significantly temperature dependent. Extensive studies of alkyl radicals^{21,22}

have shown that β -hfs follow a Karplus type relationship (17):

$$a(H^\beta) = A + B \cos^2 \theta \quad (17)$$

Constant A is small (<0.4 mT) and can often be neglected; B is ≈ 5.0 mT for C-centered radicals. There are two particular cases: (i) $R_2C^\bullet-CH_2^\beta R'$ where there are two β -H-atoms and (ii) $R_2C^\bullet-CH^\beta R_2'$ with one β -H-atom. For (i) the value of θ is 60° when R' eclipses the π -orbital (**4**) and 30° when the conformation is staggered (**3**). For free rotation, the average value of θ is 45° . If the preferred conformation is eclipsed (**4**), $a(H^\beta)$ will be in the range $A + 1/4B$ to $A + 1/2B$, and will *increase* toward the latter with increasing temperature. If the preferred conformation is staggered, $a(H^\beta)$ will be in the range $A + 3/4B$ to $A + 1/2B$ and will *decrease* toward the latter with increasing temperature. In case (ii), the limits are wider, that is, from A to $A + B$. These expectation values can be useful for determining the preferred conformation about the $C^\alpha-C^\beta$ bonds of nonrigid radicals. For example, the EPR spectrum of the *n*-propyl radical displayed $a(H^\alpha) = 2.21$ and $a(H^\beta) = 3.32$ mT at 100 K. On increasing the temperature to 200 K, $a(H^\beta)$ dropped to 2.92 mT. It follows that the preferred conformation of the *n*-propyl radical is staggered **3**. On the other hand, for the $CH_3SCH_2CH_2^\bullet$ radical $a(H^\beta)$ increased from 1.35 mT at 150 K to 1.49 mT at 205 K showing that its preferred conformation is eclipsed **4**. In general, radicals $RXCH_2CH_2^\bullet$ tend to adopt conformation **3** if X is a first row element but **4** if X is from the second or subsequent rows of the periodic table.

Longer range hfs generally decrease with the number of σ -bonds between the H-atom and UPE. Hfs from γ -H-atoms are normally much smaller [$< 1/10 \times a(H^\alpha)$]. In general, the prerequisite for observation of a substantial long-range hfs is a “frozen” conformation (on the EPR timescale). Most EPR studies of long-range hfs have involved bicyclic or polycyclic radicals in which the rigid structures place particular H-atoms at sites that are favorable for hyperfine interactions.^{23–26} For example, in the bicyclo[2.2.1]heptylsemidione radical anion **5** a large γ -hfs of 0.65 mT was observed for the indicated H^γ (Scheme 2).

Generally, γ -H-atoms for which the σ -bonds and the orbital containing the UPE adopt a “W-plan”

Scheme 2 Large long-range hyperfine interactions.

Figure 6 (a) EPR spectrum of bicyclo[1.1.1]pentyl radical **6** in liquid DTBP at 240 K. (The intensity difference of the two multiplets is due to a CIDEP effect.) (b) Spectrum of cubyl radical **7** in liquid DTBP at 245 K.

conformation (see **5** and **8**) show substantial hfs. The EPR spectra of the bicyclo[1.1.1]pentyl radical **6** and the cubyl radical **7** (Figure 6) were quite remarkable in that huge hfs of 6.96 mT were observed for the single H^γ of **6** (the intensity difference of the two multiplets is due to a CIDEP effect).^{27,28} and 0.63 mT for the single H^δ of **7**,^{29,30} because of multiple W-plan through bond and through space interactions.

Small long-range hfs are often resolvable in acyclic radicals,^{21,31,32} and in radicals containing oxygen, usually in an ether linkage.^{33–35} Many alkane radical cations in “rigid” conformations in low temperature matrices exhibit large long-range hfs.³⁶

In *n*-propane solvent, in the temperature range $90 < T < 125$ K tumbling remains fast for small to medium-sized radicals, but internal rotations may cease, so that long-range hfs can be resolved.³⁷ In the “rigid” conformations adopted at these temperatures γ -H-atoms situated trans (W-plan) with respect to the singly occupied molecular orbital (SOMO) show large hfs. For example, three of the γ -H-atoms of the neopentyl radical exhibit $a(H^\gamma) = 0.40$ mT and, even more remarkably, the unique H^γ of the 2,2,3-trimethylbutyl radical **8** had $a(H^\gamma) = 0.80$ mT.^{38,39}

4.3 Quantum Chemical Computation of EPR Parameters

The straightforward picture of just one UPE in a particular orbital interacting with nearby magnetic nuclei is a gross oversimplification.⁴⁰ In fact, radicals contain many electrons all of whose spins interact to some extent. For a more complete and accurate picture, all the populated molecular orbitals have to be taken into account in evaluating the spin density $\rho(r_n)$, which is actually the net difference between the α -spin and β -spin at the nucleus. In-depth treatments of the calculation of EPR parameters can be found in the compilation edited by Kaupp *et al.*⁴¹ Modern quantum mechanical MO packages based on DFT, or other *ab initio* methods, can compute optimum geometries of free radicals, together with the energies and eigenvectors associated with their occupied (and virtual) orbitals.^{42,43} Considerable effort has gone into finding the most effective quantum mechanical models and basis sets^{44,45} for the computation of isotropic EPR parameters.^{46–48} Methods based on the unrestricted Kohn–Sham (UKS) approach to DFT are among the most efficient. Quadratic configuration interaction (QCI) and coupled cluster (CC) methods give accurate results but are not practical for medium- or larger-sized radicals (> 10 non-hydrogen atoms). Hybrid functionals such as the popular B3LYP and the parameter-free PBE0 model provide good descriptions of the EPR spectra of many types of radicals. A combined PBE0/QCISD approach is recommended for more accurate work with species containing several heteroatoms such as nitroxides. Particular basis sets such as EPR-II,⁴⁹ and the much larger triple-zeta

quality EPR-III,⁵⁰ usually enable good agreement of computed and experimental hfs to be achieved for H-atoms. However, for heteroatoms (even the first row N, F) considerably more computational effort is often required. A number of well-tried electronic packages are now available to implement the quantum mechanics (QM) computations including GAMESS-UK,⁵¹ Jaguar,⁵² and Spartan.⁵³ The Gaussian 03 and 09 series of packages⁵⁴ are convenient because isotropic and anisotropic spin densities and hfs are directly computed and spin density maps can be plotted.

For example, the 1,3-dimethylimidazolyldihydro-boryl radical **9** was generated by H-atom abstraction from the corresponding HNC-borane and exhibited the isotropic EPR spectrum shown in Figure 7 at 245 K.⁵⁵ The molecular structure was optimized using the DFT method with the B3LYP functional and the 6-31+G(d) basis set and is shown in **9** (Figure 7). The corresponding maps of the SOMO and spin density, computed with the same geometry but the EPR-III basis set, are shown as **10** and **11**. The computed Fermi contact hfs are compared with the experimental parameters below and give a fair idea of the achievable level of agreement:

Hfs/mT	$a(2H^\alpha)$	$a(^{11}B)$	$a(2N)$	$a(2H)$	$a(6H)$

Figure 7 DFT computed structure, SOMO, and orbital spin density map of NHC-boryl radical **9**.

5 GEOMETRIES AT C $^\alpha$ OF C-CENTERED RADICALS

The ground-state structure at C $^\alpha$ of carbon-centered radicals may be planar **12** such that the UPE occupies a p -type orbital, that is, the radical has π -character. Alternatively, the radical may be pyramidal **13** such that the UPE occupies a hybrid orbital of σ -character (Scheme 3). The EPR hfs of adjacent magnetic nuclei can be very helpful in distinguishing between these alternatives. Table 1 shows experimental parameters for archetype C-centered radicals with various substituents.

The $a(^{13}C^\alpha)$ are particularly valuable because they give a direct measure of the amount of s -character in the SOMO. ^{13}C ($I = 1/2$) is present in organic radicals with a natural abundance of 1.1%; thus, signals from the interaction of UPE with this nucleus accompany the main spectrum as small satellites on either side of the main ^{12}C lines. For transient radicals, the ^{13}C satellites are usually undetectable in the noise, so isotope enrichment has to be employed. For the series of radicals $^*CH_nMe_{3-n}$, the $a(^{13}C^\alpha)$ values increase only slightly with increase in the number of Me groups (Table 1). $^{13}C^\alpha$ and H^α hfs usually show small temperature dependencies that result from vibrational motions, particularly from inversions at

Scheme 3 Geometries of π - and σ -radicals.

^ahfs in millitesla; data from Ref. 6. Note that EPR spectra give the magnitude but not the sign of hfs.

the radical center. These inversion barriers are very low, so the average structures are planar on the EPR timescale; however, pyramidal states make an increasing contribution as the number of Me groups increases.^{56,57}

For the fluoromethyl series of radicals, Table 1 shows that $a(^{13}\text{C}^\alpha)$ increases strongly as the number of F-substituents increases. Thus, the extent of pyramidity of (**13**), measured by the angle ϕ , increases as the number of F-atoms increases. The large $a(^{13}\text{C}^\alpha)$ for $\cdot\text{CF}_3$ (27.2 mT) indicates that this radical is essentially tetrahedral with the sp^3 orbital of the UPE pointing toward one corner of the tetrahedron. Note that the $a(\text{F})$ and $a(\text{H}^\alpha)$ values also increase as the radicals become more pyramidal. Inspection of the $a(^{13}\text{C}^\alpha)$ and $a(\text{H}^\alpha)$ data for radicals with oxygen substitution reveals that this element also induces pyramidity at the radical center and the same is probably true of nitrogen substituents.

The large $a(^{13}\text{C}^\alpha)$ hfs for vinyl⁵⁸ and acyl radicals⁵⁹ (Scheme 4) show that the UPE occupies orbitals with substantial s -character and that these radicals are bent. For acyl radicals $\text{RC}^\bullet = \text{O}$, the $a(^{13}\text{C}^\alpha)$ hfs increase along the series $R = \text{Me} < \text{NH}_2 < \text{O}^\text{t}\text{Bu} < \text{F}$. The degree of bending at the radical center increases with the electronegativity of the substituent, just as with alkyl radicals.

The hfs of C^α - and H^α -atoms (Scheme 4) show that cyclohexyl, cyclopentyl, and cyclobutyl radicals are essentially planar. For these ring sizes, substitution by one O-atom adjacent to the radical center induces significant pyramidity and two O-atoms induce even more s -character. By way of contrast, the $a(^{13}\text{C}^\alpha)$ and $a(\text{H}^\alpha)$ data for cyclopropyl and cyclopropenyl disclose that these radicals are bent, as is the oxiranyl radical.

Bridgehead radicals²⁶ are, of course, necessarily pyramidal and their EPR spectra show large $a(^{13}\text{C}^\alpha)$ values.⁶⁰ Interestingly, $a(^{13}\text{C}^\alpha)$ constants display a linear correlation with the NMR one bond $\text{C}^\alpha\text{--H}$ ($^1J_{\text{C--H}}$) couplings in the parent bridgehead hydrocarbons. Similar linear correlations have been found between the NMR $^1J_{\text{C--H}}$ data of methanes,⁶¹ silanes,⁶² phosphines,⁶³ and aldehydes⁶⁴ and the EPR hfs of the radicals formed by loss of the H-atoms. Morton and Preston provided atomic parameters $\psi^2(0)$, together with the isotropic hfs for unit spin density in the s -orbitals, of nuclei of the elements from He to Bi.⁶⁵ Comparison of

experimental EPR parameters with this data can be very helpful for deducing local geometries.

6 EPR STUDY OF RADICAL CONFORMATIONS AND CONFORMATIONAL INTERCHANGE

NMR spectroscopy is recognized as an extremely valuable tool for studying the conformations of molecules and biomolecules and their dynamic processes. The “timescale” of EPR is much shorter than that for NMR so that faster dynamic processes with free energies of activation much lower than those generally measurable by NMR become accessible (see **Structures and Reactivity of Radicals Followed by Magnetic Resonance**). Much important work has been carried out, mainly with proteins and other biomolecules labeled with nitroxide free radicals (see **Understanding DNA Radicals Employing Theory and Electron Spin Resonance Spectroscopy**). This section focuses on EPR studies

of the conformations of transient species. The use of Karplus type relationships for deducing preferred conformations is outlined in Section 4.2.

Small energy barriers to hindered internal rotations about $C^\alpha-C^\beta$ bonds can be determined from the experimental temperature dependences of $a(H^\beta)$. Torsion in a radical $^{\bullet}CH_2-CHR_2$ is governed by a twofold sinusoidal potential. Each well contains a number of torsional states and above each barrier there exists a set of rotational states. The observed $a(H^\beta)$ is a weighted average taken over all the populated states. Quantum mechanical methods of deriving this average are described by Fessenden^{66,67} and Kochi.⁶⁸ However, for low barriers, a “classical limit” approach generally gives the same results as the more cumbersome quantum mechanical procedures.^{69,70} The barrier to rotation about the $C^\alpha-C^\beta$ bond (V_0) can be estimated by fitting the observed temperature dependence of $a(H^\beta)$ with values calculated from (18):

$$a(H^\beta) = A + \frac{1}{2}B + \frac{1}{2}B \cos 2\theta_0 \left[\frac{I_1(\lambda)}{I_0(\lambda)} \right] \quad (18)$$

where $I_1(\lambda)$ and $I_0(\lambda)$ are modified (hyperbolic) Bessel functions, $\lambda = V_0/kT$, and θ_0 is the value of θ at the potential minimum. (For $V_0 < \text{circa } 2.5 \text{ kJ mol}^{-1}$ (20) may be approximated by: $a(H^\beta) = A + \frac{1}{2}B + \frac{1}{2}B \cos 2\theta_0[\lambda/2 - \lambda^3/16]$.) A and B are known from the Karplus equation and V_0 is varied so as to obtain the best fit between experimental and calculated $a(H^\beta)$ over the accessible temperature range. By these means, barriers, generally in the range $5.0 > V_0 > 1.0 \text{ kJ mol}^{-1}$, have been obtained for many alkyl radicals.

Internal rotation barriers higher than $\sim 10 \text{ kJ mol}^{-1}$ generally lead to selective line broadening in X-band EPR spectra. (EPR observation of selective line broadening also depends on the magnitude of the difference in the hfs of the exchanging magnetic nuclei.) This occurs when the lifetimes of the conformational states become comparable to the reciprocal of the difference in the hfs of two exchanging H-atoms. When the barrier to internal motion is higher still, separate EPR spectra will be observed for each conformational state. Pioneering EPR studies were undertaken on the conformations of persistent cyclic-semidiones⁷¹ and nitroxides.^{72,73} EPR data for transient cyclic radicals including cyclohexyl,^{74,75} other cycloalkyl,^{76–78} and cycloalkenyl⁷⁹ proved useful for charting the

Figure 8 CW EPR spectra from cycloalkylmethyl and cyclohexylacyl radicals. (a) Spectra of cyclohexylmethyls **14e,a** at 240 K in *t*-BuPh solution. (b) and (c) second derivative spectra of 4-*t*-butylcyclohexyl radicals **16e,a** at 140 K in cyclopropane.

conformational changes caused by the introduction of the planar radical center into each type of ring.

A valuable EPR spectroscopic technique for studying the conformations of rings, unperturbed by the presence of a planar radical center, involves using the $CH_2^{\bullet}$ moiety as a spin probe.⁸⁰ The small, neutral, CH_2 group of a cycloalkylmethyl radical, $c-C_nH_{2n-1}CH_2^{\bullet}$, causes minimal perturbation of the adjacent ring. The cyclohexylmethyl radical exists as a pair of conformers **14e** and **14a** in which the $CH_2^{\bullet}$ group is in the equatorial and axial orientations, respectively. The EPR spectrum of the cyclohexylmethyl radical (Figure 8a) showed a large double triplet (E) for the equatorial radical **14e** accompanied by a minor amount of a second double triplet (A) for the axial radical. The main difference was that the axial radical **14a** had a larger doublet hfs from H^β and this enabled the two spectra to be resolved. Steric hindrance from the *syn*-axial hydrogens (H^δ) of **14a** resulted in an increased torsional barrier and consequently the large H^β hfs. From the relative concentrations of the two species **14e** and **14a**, the conformational free energy difference of the $CH_2^{\bullet}$ group ($-\Delta G_{300}^0$) was found to be 3.0 kJ mol^{-1} . The method was also applicable to cycloalkylmethyl radicals with ring sizes up to at least 15,⁸¹ to cycloalkenylmethyl radicals (**15e,a**, Scheme 5),⁸² and to cyclohexylacyl radicals (**16e,a**)⁸³ (Scheme 5, Figure 8b and c).

Scheme 5 Axial and equatorial cycloalkylmethyl and cycloalkylacyl radicals.

7 EXCHANGE BROADENING AND INTERNAL MOTIONS

Section 1.3 established that, for radicals in solution, spin-state lifetimes are governed by spin–spin relaxation phenomena with characteristic time τ_2 . For Lorentzian lines, and with power well below saturation, (10) yields $\Delta B_{1/2} = 2/\gamma_e \tau_2$. Internal rotations, ring inversions, and other intramolecular processes alter the electron spin–nuclear spin interaction and hence can drastically modify τ_2 . Some lines, but not others, may be selectively broadened, depending on the type of motion. Since the rates of internal motions depend on temperature, the EPR linewidths of such radicals are also temperature dependent. The amplitude of a given line in a first derivative spectrum is inversely proportional to the square of the linewidth, so small changes in the latter can lead to striking changes in spectral appearance. For example, the hydroxymethyl radical exists as a 1 : 1 mixture of the 2 equiv planar conformations **17a** and **17b** at low temperatures. In the slow exchange limit at 150 K (Figure 9), the EPR spectrum appears as a double, double doublet from interaction of the UPE with two nonequivalent H^X and H^Y and the

Figure 9 Temperature-dependent linewidths in the EPR spectrum of HO–CH₂•.

Scheme 6 Interchange of the two planar conformers of the hydroxymethyl radical.

hydroxyl hydrogen H^β (Scheme 6; $a(H^X) = 1.765$, $a(H^Y) = 1.853$, $a(H^{\beta}) = 0.216$ mT).⁸⁴ At a high enough temperature, torsions about the C–O bond are fast leading to rapid exchange of H^X and H^Y. In the fast exchange limit at >200 K, H^X and H^Y are equivalent and the spectrum is a sharp triplet of doublets.

At intermediate temperatures, broadening of the central lines appears. Maximum broadening (coalescence) is reached at about 165 K, where the rate of interchange of H^X and H^Y is equal to the frequency separation of the inner lines ($a(H^Y) - a(H^X) = 0.088$ mT = 0.25×10^6 Hz).

When exchange broadening is due to interchange of two species of equal energy, as with **17a** and **17b**, the forward and backward rate constants (k) are equal. The rate constant for interchange can be simply derived from the difference in the hfs of H^X and H^Y and the linewidth.⁸⁵ Other kinds of selective EPR line broadening with different characteristics are attributable to different types of internal motions.⁸⁶ Software, based on relaxation matrix theory, can be obtained for simulating the line broadening of more complex processes.⁸⁷

Scheme 7 “Frozen” conformer of the neopentyl radical.

The neopentyl radical **18** provided a particularly striking example of exchange broadening.⁸⁸ Above 210 K, the internal rotations about the $C^\alpha-C^\beta$ bond, and about the three $C^\beta-C^\gamma$ bonds, are all in the fast exchange limit, so the solution EPR spectrum of **18** consists of a triplet ($a(2H^\alpha) = 2.14$ mT) having each component split into 10 lines from the 9 equiv H^γ ($a(9H^\gamma) = 0.096$ mT). In the temperature range 210–106 K, exchange broadening is observed as a result of hindered rotation of the three Me groups about their $C^\beta-C^\gamma$ bonds (Figure 10). By 96 K, the “rigid” conformation **18a,b** is reached, in which the Me group rotations are frozen with 3 equiv trans $H^{\gamma t}$ having large hfs because they are in W-plan sites ($a(3H^{\gamma t}) = 0.404$ mT) and 6 equiv gauche $H^{\gamma g}$ ($a(6H^{\gamma g}) = 0.062$ mT). Internal rotation about the $C^\alpha-C^\beta$ bond continues rapidly even at 96 K because of the low sixfold barrier. Figure 10 shows

a selection of exchange broadened experimental EPR spectra in the range 106–210 K alongside computer simulations obtained with a three-jump model having all forward and reverse rate constants equal. An Arrhenius plot of the rate constants yielded an activation barrier of 15.4 kJ mol⁻¹ and a pre-exponential factor of $10^{12.6}$ s⁻¹ for the internal Me rotations. Activation barriers in the range 8–40 kJ mol⁻¹ for group rotations about C–C,^{22,37} C–N,^{89,90} and C–O bonds have been determined by similar means as well as inversion barriers for several types of rings.^{79,80,82,91}

8 EPR SPECTRA OF HETEROATOM-CENTERED RADICALS

Isotropic EPR spectra have been described for many types of radicals containing elements from the first and second rows of the periodic table. This subsection surveys radicals in which the UPE resides mainly on a particular heteroatom and those in which spin is partly delocalized away from the principal heteroatom. Anisotropic spectra have been obtained from many radicals centered on elements from the third and subsequent rows of the periodic table,^{92,93} but solution spectra tend to be broad, and comparatively few have been reported.

Figure 10 EPR spectra of the central component of the triplet from the neopentyl radical (**18**). Left: Experimental spectra at the indicated temperatures. Right: Simulated spectra with the indicated rate constants. [Adapted with permission from K. U. Ingold, *et al.*, *J. Phys. Chem.*, 1986, **90**, 2859–2869. Copyright 1986 American Chemical Society.]

8.1 Spectra from Transient Boron- and Aluminum-Centered Radicals

Triarylboron radical anions $[\text{Ar}_3\text{B}]^{\cdot-}$ are of interest because they are isoelectronic with neutral C-centered radicals $\text{Ar}_3\text{C}^{\cdot}$. Early EPR studies showed that $[\text{H}_3\text{B}]^{\cdot-}$ (**19**) had $a(^{11}\text{B}) = 1.99 \text{ mT}$ and $a(3\text{H}) = 1.52 \text{ mT}$ ⁹⁴ while for the analog **20** $a(^{11}\text{B}) = 0.78 \text{ mT}$ was obtained.⁹⁵ The UPE is mainly on boron and the low $a(^{11}\text{B})$ values suggest that these are π -type species with planar geometry at boron.^{94,96} Other classes of transient boron-centered radicals that have been extensively studied by EPR spectroscopy in solution include the phosphine-boryl radicals (**21**),^{97,98} dialkyl sulfide-boryl radicals (**22**),⁹⁹ and amine-boryl radicals (**23**).^{100–103} These species were generated by H-atom abstraction from the corresponding ligated boranes and gave rise to well-defined spectra often showing structure from ^{10}B ($I = 3$, 19.9%) as well as ^{11}B ($I = 3/2$, 80.1%); see Figure 11a.^{104,105}

The equilibrium geometries of the boron centers of **21** and **22** (Scheme 8) are planar, or nearly so, as judged by the ^{11}B and H^α hfs (Table 2). In contrast to this, the larger ^{11}B hfs of amine-boryls **23** (Table 2) indicated a pyramidal arrangement of the ligands about boron.

EPR spectroscopy showed the amine boryl radicals **23** to be the most reactive; they underwent β -scission more readily than isoelectronic alkyl radicals and rearranged rapidly to aminyl-borane radicals. Their nucleophilic character was confirmed by a laser flash photolysis (LFP) study of the kinetics of various reactions.¹⁰⁶

Figure 11 (a) EPR spectrum of the $(\text{MeO})_3\text{P} \rightarrow \text{B}^{\cdot}\text{HBu}-t$ radical at 240 K in cyclopropane showing signals from ^{11}B and ^{10}B containing isotopomers ($a(^{11}\text{B}) = 1.34$, $a(^{10}\text{B}) = 0.45$, $a(\text{H}^\alpha) = 1.55$, $a(^{31}\text{P}) = 3.96$, $a(9\text{H}) = 0.09 \text{ mT}$).¹⁰⁴ (b) EPR spectrum of the α -tocopheroxyl radical **49**.

Scheme 8 Selected boron-centered radicals and ions.

N-Heterocyclic carbene boryl radicals containing imidazole and triazole rings were generated by H-atom abstraction from the corresponding *N*-heterocyclic carbene boranes,^{55,107} and by reduction of analogous cations.¹⁰⁸ The isotropic EPR parameters of model **24** (Table 2) and others, together with DFT computations, showed them to be planar π -delocalized species, in which the UPE is delocalized from boron into the π -system of the adjacent heterocyclic rings. Kinetic EPR studies revealed that their bimolecular self-termination and halogen abstraction reactions were strongly influenced by steric shielding of the boron center.

Apart from anisotropic EPR studies,^{109,110} a few alane radical anions were generated in solution by H-atom abstraction from MX_3AlH salts.¹¹¹ Comparison of the $a(^{27}\text{Al})$ hfs ($I_{\text{Al}} = 5/2$) for $\text{AlH}_3^{\cdot-}$ (Table 2) with that calculated for unit population of the Al 3s orbital (98.5 mT)¹¹² showed that its semi-occupied orbital has about 16% 3s character so that it deviates somewhat from planar.

8.2 Spectra from Transient Silicon-, Germanium-, and Tin-Centered Radicals

Spectroscopic studies of silyl radicals have often been plagued by the buildup, during photolysis, of spectra from secondary persistent radicals that mask transient species. In many spectra, the satellites from ^{29}Si [natural abundance 4.7%, $I(^{29}\text{Si}) = 1/2$] were observed, and the EPR parameters for some model radicals are listed in Table 3.^{113–119} The values of $a(^{29}\text{Si})$ for $\text{H}_3\text{Si}^{\cdot}$ and alkylsilyl radicals ($\sim 18 \text{ mT}$) are $\sim 25\%$ that expected for unit UPE population of the Si 3s orbital ($\sim 80 \text{ mT}$). Therefore, the SOMO of these radicals has about

^aData from anisotropic solid-state spectra.^bAr = mesityl.

1/4 s-character and the radicals are pyramidal (**25**, Scheme 9), in contrast to the related C-centered radicals. Introduction of an electronegative ligand X (such as F or OH) confers greater p-character on the Si–X bond and correspondingly greater s-character on the remaining Si–H bonds and the SOMO. The pyramidal character is increased and both *a*(H^α) and *a*(²⁹Si) are increased (Table 3). The introduction of phenyl substituents does not greatly affect the configuration at Si but there is significant delocalization of unpaired spin into the aromatic rings. It was shown that for a good range of species a linear relationship exists between *a*(²⁹Si) and ¹*J*(SiH) of the parent silanes.¹²⁰

EPR spectra have also been obtained for a significant number of germanium- and tin-centered radicals (Table 3). Comparison of the ⁷³Ge (*I* = 9/2, 7.8%) and ^{117,119} Sn (*I* = 1/2, 7.6, 8.6%) hfs with the expected values for unit occupation of the 4s or

with alkyl radicals. Only a few primary alkylaminyls RHN[•] have been detected in solution, but primary arylaminyls ArHN[•] and many secondary alkylaminyls and arylaminyls have been studied; EPR parameters for a selection of model species are displayed in Table 4.^{121–132}

The data indicate that alkylaminyl radicals are bent and that in arylaminyls the UPE is delocalized into the aromatic rings. The ground-state structures of the simple aminium radical cations are planar (**28**), unlike the pyramidal parent amines. Alkoxyaminyl and thioaminyl radicals have smaller *a* (¹⁴N) values than aminyls as might be expected. Amidyl radicals (acylaminyls) have larger *a* (¹⁴N) and the temperature dependence of the *a* (H^β) of model radicals showed that they have π -type structures **29** (Scheme 10).^{131,133,134}

Iminyl radicals (R₂C=N[•]) are isoelectronic with vinyl and formyl radicals **30**¹³⁵ (Scheme 10). These are all σ -type radicals but the UPE in formyl is contained in an orbital with substantial s-character (**30**), whereas the SOMO of iminyls has practically pure p-character (**31**, **32**). EPR data is set out in Scheme 10 for methaniminyl **31**,¹³⁶ and model iminyls **32**,¹³⁷ **33**,¹³⁸ and **34**.¹³⁹ Numerous more complex iminyls have been characterized by EPR spectroscopy and the kinetics of their cyclization reactions has been investigated^{140,141} (see **Radical Kinetics and Clocks**).

Several N-based species in which the UPE is shared between two or more N-atoms are

important organic intermediates. Hydrazyl radicals are derivatives of hydrazine, and the EPR data for the parent **35**,¹⁴² and analogs **36**¹⁴³ and **37**¹³⁶ (Scheme 10) show that the UPE is fairly evenly distributed between both N-atoms, probably because of a contribution from structures R₂N–NH[•] $\leftrightarrow$ R₂N^{•+}=NH[–]. Otherwise, hydrazyls resemble aminyls and the geometry is flattened at both N-atoms, as required by their π -structures. Sample EPR data is also displayed in Scheme 10 for diazenyl radical **38**,^{144,145} and triazenyl **39**¹⁴⁶ in which the UPE is also distributed to all the N-atoms. Huge varieties of aminoxyl radicals (nitroxides, R₂N–O[•]) and iminoxyl radicals (R₂C=NO[•]) have been investigated and many are persistent or stable (see **Nitroxide-Mediated Polymerization and its Applications** and **Nitroxides in Synthetic Radical Chemistry**). Their EPR spectra are outside the scope of this article.¹⁴⁷

Scarcely any alkylphosphinyl radical R₂P[•] has been observed in fluid solution but Ph₂P[•] [*a* (³¹P) = 7.87 mT] has been detected in the solid phase at low temperatures.¹⁴⁸ A few phosphonyl radicals, such as (EtO)₂P[•]O [*g* = 2.0018, *a* (³¹P) = 68.86 mT], have also been characterized.¹⁴⁹ In contrast to this, many phosphoranyl radicals (R₄P[•]), mostly generated by addition of neutral radicals to phosphorus(III) compounds, have been studied by EPR spectroscopy.^{150,151} The spectra reveal that the local geometry around phosphorus varies markedly, depending on the nature of the attached ligands.^{152,153} At one extreme, the majority of

Scheme 10 Structures and EPR parameters for N-centered radicals and related species (see text for source references).

phosphoranyls adopt trigonal bipyramidal structures **40–45** (Scheme 11) with two ligands apical, two equatorial, and the final equatorial position occupied by an orbital lobe (TBP). The large hfs for ^{31}P and apical ligands (Scheme 11) show that most of the spin density is associated with these sites. The principal atomic orbitals that contribute to the SOMO of TBP phosphoranyls are illustrated in **44b** and **45b**. At the other extreme, some phosphoranyls such as $\text{Ph}_3\text{P}^+\text{Cl}^-$ adopt structures such as **46** with local C_{3v} symmetry at phosphorus.¹⁵⁴ In this case, the SOMO is a $\text{P}-\text{Cl}\sigma^*$ orbital as shown in **46** (Scheme 11).¹⁵⁵ Quantitative information about

Scheme 11 EPR parameters for phosphoranyl radicals (see text for source references).

ligand apicophilicities, stereochemical permutations, β - and γ -scission processes, and other reactions has been obtained by EPR methods for many phosphoranyls.

8.4 Spectra from Transient Oxygen- and Sulfur-Centered Radicals

Hydroxyl ($\text{HO}^\bullet$) and alkoxyl ($\text{RO}^\bullet$) are not detectable in solution because of unsuitable relaxation times. Aryloxy radicals, semiquinone, and semidione radical anions are very important biochemical species and many derived from phenolic natural products have been examined by EPR

Scheme 12 Structures and EPR parameters of radicals centered on oxygen and sulfur.

spectroscopy. EPR parameters for phenoxyl **47** and the aryloxyl **48**, derived from the artificial antioxidant BHT, are displayed in Scheme 12.¹⁵⁶ The well-resolved spectra that can be obtained are typified by that from the chromanyloxyl radical **49** derived from the natural antioxidant α -tocopherol (Figure 11b). The EPR parameters show that these are π -type species in which spin is extensively delocalized.

Peroxy radicals ($\text{ROO}^\bullet$) are easily formed by the extremely rapid coupling of C-centered radicals with dioxygen. Signals from peroxy radicals often accompany the EPR spectra of alkyl radicals unless all traces of oxygen are excluded. They are easy to identify because of their comparatively large g -factors (~ 2.015). EPR spectra of peroxy radicals have been observed from a wide range of compounds including alkanes, alkenes, substituted alkanes, lipids, aromatics, and others.^{157,158} The spectra are usually broad, and linewidths are highly dependent on temperature, solvent viscosity, and the presence of

Figure 12 EPR spectrum of the cyclohexylperoxyl radical **51** in cyclopropane at 150 K. (a) First derivative spectrum. (b) Second derivative spectrum.

residual oxygen. Figure 12 shows the spectrum of the cyclohexylperoxyl radical **51** in first and second derivative modes.¹⁵⁹

The isotropic hfs of peroxy ^{17}O isotopomers^{160,161} (Scheme 12) indicate that spin density is partitioned between both oxygens, but more resides on the terminal O^1 . The structures **50a,b** give a reasonable representation of the SOMO showing that peroxy radicals are π -radicals.

EPR spectra for thiyl radicals ($\text{RS}^\bullet$) and sulfinyl radicals ($\text{RSO}^\bullet$) have only been obtained in low temperature matrices. However, well-resolved solution EPR spectra have been recorded for sulfonyl radicals ($\text{RS}^\bullet\text{O}_2$) generated in a variety of ways¹⁶² from sulfinic acids,¹⁶³ sulfonyl chlorides, and sulfonate esters (Scheme 12). The hfs disclose spin distribution that is typical of radicals with a pyramidal center at sulfur (**52**, **53**).^{164,165}

9 KINETIC EPR SPECTROSCOPY

9.1 Radical Decay Curves and Concentration Measurement

The growth and decay of EPR signals can be monitored as a function of time when the EPR setup entails radical generation by UV light (or other radiation). When the irradiation commences, the signal grows in and on shuttering the light the signal decays. Figure 13 shows a typical experiment in which the NHC-boryl radical **55** was generated from irradiation of the NHC-BH_3 precursor and DTBP in the EPR resonant cavity. The CW spectrum shown was recorded and then the field was set to the value

Figure 13 First derivative EPR spectrum of radical **55** in PhBu-*t* at 245 K; the inset shows the growth and decay of the signal as a function of time. The integral and double integral (DI, red) are shown beneath.

near the maximum signal intensity marked by an arrow. The spectrometer time constant was adjusted to a value much less than the half-life of the radical ($t_c = 1.28$ ms). Time scans then enabled growth and decay curves such as that shown in the inset to be obtained.

Absolute radical concentrations are usually needed for kinetic information to be deduced from such decay curves. According to (9) (Section 1.3), the power absorbed by a sample is proportional to the imaginary part of the susceptibility (χ''), and hence to the number of paramagnetic species present. The radical concentration is therefore proportional to the integral of the absorption curve, or the double integral of the first derivative spectrum. For dependable concentration measurements, the spectral data must be obtained on samples of volume less than or equal to the sensitive volume of the cavity and for signals below microwave power saturation. The concentration of a particular radical $[R^*]$ can be obtained by comparing its double integral DI_R to that of a known concentration of a standard persistent radical (S^*) such as

DPPH or galvinoxyl (DI_S). The microwave power, modulation amplitude, receiver gain, scan range ($\Delta H_R/\text{mT cm}^{-1}$), and temperature of the particular radical (T_R/K) are noted. The same sample tube is then filled to the same level with the standard solution which is then scanned under similar conditions at the same power and modulation amplitude. The concentration of R^* can then be obtained from (19):

$$[R^*] = [S^*] \times \frac{DI_R}{DI_S} \times \frac{\text{Gain}_S}{\text{Gain}_R} \times \frac{\Delta H_R^2}{\Delta H_S^2} \times \frac{\text{Ruby}_S}{\text{Ruby}_R} \times \frac{T_R}{T_S} \times F \quad (19)$$

The term $\Delta H_R^2/\Delta H_S^2$ equals 1.0, except when the spectrum of R^* was recorded with a field scale different from the standard. T_R/T_S allows for any temperature difference between the particular radical and the standard. If R^* was in a solvent different from the standard, variations in cavity Q can be corrected for by normalizing the R^* and S^* spectra with respect to the signal (at circa 200 mT) from a single crystal of synthetic ruby, positioned off-center in the microwave cavity. The ruby term can usually be neglected if R^* and S^* were both in hydrocarbon solvents. The whole S^* spectrum is doubly integrated but, if only a fraction of the R^* signal was accessible, then the multiplier F converts to the DI of the entire R^* spectrum.

Most small, unhindered, neutral radicals decay in fluid solutions with half-lives within 1–2 ms. A special technique that enables many identical radical decays to be collected and averaged, so as to improve signal to noise ratio, was devised for this situation.⁶⁷ Applications of the technique to many diverse kinetic problems were reported by Ingold and coworkers in an outstanding series of papers.^{166–168}

In the absence of a suitable reaction partner, most radicals decay by combination and disproportionation processes which are second order in radical concentration. Fischer and coworkers enhanced the kinetic EPR method in several ways and developed a modulation approach.^{169,170} The rate constants they obtained for alkyl radical terminations ($2k_t$) in many different solvents are among the most accurately known. This data established that the termination rates of small radicals are inversely proportional to solvent viscosity and that these processes are diffusion controlled,¹⁷¹ which results in $2k_t \approx 5 \times 10^9$

$\text{M}^{-1}\text{s}^{-1}$ in fluid solvents at ambient temperature. The rate constant ($2k_t = 8.7 \times 10^9 \text{ M}^{-1}\text{s}^{-1}$ at 298 K) and Arrhenius parameters for *t*-butyl radical termination in *n*-heptane:¹⁷² $\log(2k_t/\text{M}^{-1}\text{s}^{-1}) = 11.63 - 9.61 (\text{kJ mol}^{-1})/2.3 \text{ RT}$ have been widely used as “clock” parameters for calibrating the dynamics of other radical reactions. Kinetic EPR is usually less precise than LFP but has the advantages of good resolution and high specificity. KEPR does not require the potentially awkward reporter chromophores in radicals that are needed with the LFP method (see **Radical Kinetics and Clocks**).

Termination rate constants and equilibrium constants for radical–dimer equilibria have been obtained for many classes of radicals,¹⁷³ including B-centered radicals,^{55,100} a huge range of C-centered radicals with many different structural features,^{58,174–176} as well as other group 14 element-centered radicals.¹⁷⁷ Similarly, the terminations of N- and P-centered radicals including aminyls,^{178,179} amidyls,¹⁸⁰ iminyls,^{141,181} alkoxyaminyls,¹⁸² diazenyls,¹⁴⁵ and phosphoranyl,^{151,183,184} have been investigated by EPR. The terminations and radical–dimer equilibria have also been examined for numerous O-centered species including phenoxyls^{185,186} and peroxy.^{187–189} Most of the latter, particularly secondary and tertiary alkylperoxy, terminate many orders of magnitude more slowly than the diffusion limit.¹⁹⁰

An alternative EPR-based method of studying reaction dynamics relies on the increase of ESR linewidths that results from decreasing lifetime of the observed radicals.^{191,192}

9.2 Steady-State Kinetic EPR Measurements

UV photolysis of DTBP, neat or in solution, produces *t*-BuO $\cdot$ radicals that are EPR “silent” and so do not complicate EPR spectra. In the presence of two substrates HR¹ and HR² (or two sites in the same substrate), unselective abstraction gives rise to two radicals that are destroyed by bimolecular processes. The steady-state system can be represented by (20)–(24):

Provided both radicals are transient and terminate at the diffusion-controlled limit ($k_{22} = k_{23} = k_{24}$), the following relation holds:

$$\frac{k_{20}}{k_{21}} = \frac{[\text{R}^1\cdot][\text{HR}^2]}{[\text{R}^2\cdot][\text{HR}^1]} \quad (25)$$

The concentrations of HR¹ and HR², and/or the temperature, are adjusted until, under conditions of steady-state photolysis, spectra of both radicals can be simultaneously recorded. The rate constant ratio k_{20}/k_{21} can then be determined from the known substrate concentrations and the ratio $[\text{R}^1\cdot]/[\text{R}^2\cdot]$ obtained from the EPR spectra. The relative rate data can be put on an absolute scale by using a standard radical “clock,” such as cyclopentane plus *t*-BuO $\cdot$,¹⁹³ as a reference reaction. Many suitable radical clocks¹⁹⁴ have been calibrated and compilations of rate data are available^{173,195–197} (see **Radical Kinetics and Clocks**).

The dynamics of a unimolecular reaction of a radical (U $\cdot$) to some rearranged radical (R $\cdot$) can be probed when the species is generated from some photolabile precursor XU in the absence of substrates.

Under steady-state conditions relationship (26) is easily derived:

$$\frac{1}{[\text{R}\cdot]} = \frac{2k_{\text{UR}}}{k_r} + \frac{2k_{\text{RR}}[\text{R}\cdot]}{k_r[\text{U}\cdot]} \quad (26)$$

In principle, the radical concentrations can be varied by changing the incident UV intensity.

A plot of $1/[R^*]$ against $[R^*]/[U^*]$ then produces a line of slope $2k_{RR}/k_t$ and intercept $2k_{UR}/k_t$. In practice, the EPR signals are usually too weak to allow a sufficient change of radical concentrations for accurate determinations. If, however, both U^* and R^* terminate at the diffusion-controlled limit, then $2k_{UR} = 2k_{RR} = 2k_t$ and (26) simplifies to

$$\frac{k_r}{2k_t} = [R^*] + \frac{[R^*]^2}{[U^*]} \quad (27)$$

and hence $k_r/2k_t$ can be determined simply from EPR measurements of the U^* and R^* concentrations. If R^* terminates at the diffusion-controlled limit then it is usually accurate enough to use Fischer's $2k_t$ data for *t*-Bu $\cdot$ in *n*-heptane,¹⁷² corrected for the difference in the viscosities of *n*-heptane and the solvent used.¹⁹⁸

Rate constants for many dissociations including decarbonylations^{199,200} and other β -scission processes^{201,202} have been obtained by this method. For example,²⁰³ *i*-propylthiyl radicals, generated by UV photolysis of the corresponding disulfide, added

Scheme 13 β -Scission of thioimidoyl radical **56** and ring-opening reactions of mono- and poly-cycloalkylmethyl radicals.

Figure 14 EPR spectra and double integrals of thioimidoyl **56** and *i*-propyl radicals at different temperatures. (a) At 190 K; (b) at 210 K; and (c) at 230 K. The * indicates the central components of the *i*-propyl radical spectrum.

to cyclohexane isonitrile to produce thioimidoyl radicals **56** (Scheme 13). The EPR spectrum of **56** was observed in cyclopropane solution at $T < 180$ K (Figure 14a). Above ~ 190 K, the spectrum of **56** was accompanied by that of the *i*-propyl radical (Figure 14b) and at $T > 240$ K only the *i*-propyl radical could be discerned. This sequence of spectra was reversible on lowering the temperature. The concentrations of **56** and *i*-propyl were obtained at each temperature from the double integrals of the spectra shown in Figure 14 and by use of (19). Then the $k_d/2k_t$ values at each temperature were derived from (27) and, after inclusion of Fischer's $2k_t$ data, gave $\log(A_d/s^{-1}) = 12.1$, $E_d = 38 \text{ kJ mol}^{-1}$ for the dissociation of **56**.

Analogous steady-state EPR methods (SEPR) have been applied to the study of ring opening of cyclopropylmethyl (**58**),^{204,205} cyclobutylmethyl (**59**), cyclobutenylmethyl radicals,^{206–208} and domino ring-opening reactions of bicyclo[1.1.1]pentylmethyl (**60**),²⁰⁹ cubylmethyl (**61**),²⁹ and analogs.^{210,211} SEPR investigations of the kinetics of other types of rearrangements,

Figure 15 EPR spectra from photosensitized UV irradiation of oxime oxalate amide **62** in *t*-BuPh. High and low field 1 : 1 : 1 triplets are from $\text{PhCH}=\text{N}^\bullet$ (**63**). The carbamoyl radical is marked by **A** and the azetidinylaminy radical is marked by **C**. (a) Spectra at 220 K. (b) Spectra at 240 K. (c) Spectra at 310 K. [Adapted with permission from G. A. DiLabio, *et al.*, *Org. Lett.*, 2005, 7, 155–158. Copyright 2005 American Chemical Society.]

including aryl group migrations,²⁰⁴ and ring-closure reactions,^{136,212,213} have also been published. An example is the SEPR determination of the rate constant of an unusual 4-exo-cyclization as illustrated in Figure 15. Photolysis of oxime oxalate amide **62**, sensitized with 4-methoxyacetophenone, in *t*-butylbenzene at 220 K yielded the phenyliminyl radical **63** and carbamoyl radical **A** (Scheme 14).²¹⁴

Phenyliminyl **63** appeared as a pair of 1 : 1 : 1 triplets one in either wing of the EPR spectrum (Figure 15). Carbamoyl **A** contributed a 1 : 1 : 1 triplet in the central region (Figure 15a). As the temperature was raised, 4-exo-cyclization of **A** into the oxime ether acceptor became important and yielded azetidinylaminy radical **C**. The signals from **C** ($g = 2.0049$, $a(\text{N}) = 1.37$, $a(1\text{H}) = 1.37$, $a(2\text{H}) = 0.25$, $a(2\text{H}) = 0.10$ mT) dominated the EPR spectrum at $T = 310$ K (Figure 15c). The rate constant for cyclization of **A** was found to be $3 \times 10^4 \text{ s}^{-1}$ at 300 K.

Scheme 14 4-exo-Cyclization of a carbamoyl radical onto an oxime ether acceptor.

10 DETERMINATION OF THERMODYNAMIC PARAMETERS BY EPR SPECTROSCOPY

Radical enthalpies of formation ($\Delta H_{f,300}$), radical stabilization enthalpies (RSEs), and bond dissociation enthalpies [BDE(R–X)] are useful parameters for assessing mechanisms and for planning syntheses. *Relative* thermodynamic parameters can be obtained from EPR measurements of radical concentrations in “radical buffer” systems^{215,216} where an equilibrium is set up between two related radicals and their precursor molecules. The method has been successfully applied for the determination of thermodynamic data for alkanes and alkyl radicals,^{217,218} phenols and aryloxy radicals,^{219,220} pyridinols,^{221,222} and pyrimidinols.²²³

Many moderately stable free radicals exist in solution in equilibrium with their dimers. The equilibrium constants of many such systems have been determined from EPR measurements of the radical concentrations.²²⁴ Rüchardt used BDE(C–C) values derived from equilibrium data to produce a self-consistent set of RSEs that tend to express the difference in stability of a pure hydrocarbon radical $\text{L}_3\text{C}^\bullet$ ($\text{L} = \text{H}$, alkyl) and the corresponding substituted radical $\text{L}_2\text{SC}^\bullet$ ($\text{S} = \text{functional group}$).²²⁵ A good number of empirical relationships between RSEs and spin densities have been suggested.^{226–228} The most comprehensive treatment based on H^α hfs from planar mono- and disubstituted radicals^{229,230}

Scheme 15 Internal rotation in functionalized primary radicals.

gave the following relationships for RSE and BDE (kJ mol^{-1}) where the $a(\text{H}^\alpha)$ are in millitesla:

$$\text{RSE} = 69.0a(\text{H}^\alpha) - 155.0 \quad (28)$$

$$\text{BDE}(\text{C}-\text{H}) = 67.3a(\text{H}^\alpha) + 260.8 \quad (29)$$

Linear relationships were also found for tertiary radicals involving the hfs from β -Me groups.

Another empirical EPR method for BDEs focuses on the torsion barriers (E_0) about the C–X bonds in primary radicals of type $\text{L}_n\text{XCH}_2^\bullet$ (**64**, Scheme 15).^{231–233}

The linear relationship (updated for recent BDE data) found between the two quantities is shown in (30).^{234,235}

$$\text{BDE}(\text{L}_n\text{XCH}_2-\text{H})/\text{kJ mol}^{-1} = 422.6 - 0.86E_0 \quad (30)$$

The correlation has proved useful for estimating and/or checking BDE data in a variety of circumstances.^{230,236}

11 CONCLUSIONS

Isotropic EPR spectra yield invaluable information about a radical's identity, the principal site of its UPE, and how this UPE is distributed around the structure. A very effective partnership with DFT computations enables dependable information about molecular structure and the nature of the frontier orbitals to be deduced. EPR concentration measurements also enable the dynamics of many processes to be quantified. This information is of outstanding service in deducing or supporting reaction mechanisms and as a tool for planning novel syntheses.

1 INTRODUCTION

Radicals are chemical species containing at least one unpaired electron in an atomic or molecular orbital. The importance of this class of reactive intermediate has been duly noted in chemical and biological systems.^{1,2} An understanding of the reactivity of radicals has allowed for a better understanding of biochemical pathways in cells and the cause of many diseases.^{3,4} Exploitation of the properties of radicals has provided efficient procedures for synthesizing novel molecular and polymer materials.^{5,6} Of the many pathways available to radicals, the mere loss or gain of a single electron is of tremendous consequence as it yields an even-electron species with different reactivity properties. Hence, knowledge of the redox properties of radicals is imperative for predicting the feasibility for an electron transfer reaction.⁷ Furthermore, accurate knowledge of the standard potentials of free radicals also allows for the estimation of other pertinent thermodynamic information, such as pK_a s and bond dissociation energies, that may not be otherwise readily available.⁸

The ionization potential and the electron affinity of a radical are a measure of its donor and acceptor properties in the gas phase. The oxidation and reduction potential of a radical are a measure of the donor and acceptor properties in the solution phase. In solution, the properties of the solvent contribute to some variation in the oxidation and reduction potentials mainly due to differences in the solvation properties. This article focuses on the redox properties

of radicals measured in solution and on the electrochemical and photoelectrochemical methods used to investigate and characterize them.^{9–15} The article concludes with up-to-date tables of standard reduction and oxidation potentials of radicals. The last extensive compilation of literature data was previously reported by the Aarhus group in 1999.¹³

There are several direct and indirect electrochemical methods that have been developed for the investigation of the redox properties of transient radicals, the majority of which are based on a combination of photochemical and/or electrochemical techniques. The direct evaluation of the oxidation and reduction potentials of radicals by electrochemical techniques includes cyclic voltammetry, which is by far the most widespread, and also other complementary techniques, such as polarography and second harmonic alternating current voltammetry (SHV). Photoelectrochemical techniques rely on light to homolytically cleave a covalent bond, which generates the radicals, and electrochemical means to detect and study them. The two most commonly employed photoelectrochemical methods are photo-modulation voltammetry, in which transient radicals are generated by modulated photolysis, and thermalized laser flash photolysis, in which a laser is used to inject electrons into solution by irradiation of an electrode. Although trivial to many, it is often taken for granted that no matter the analytical technique used to measure a standard potential, it is an intrinsic property of a chemical species and

therefore defined by the same fundamental principles independent of the technique employed. However, each technique has its strengths and weaknesses. Many of them are thoroughly covered in a number of books, including those by Bard and Faulker,¹¹ Wightman and Wipf,¹² and Compton and Banks.¹⁴ A brief overview of these various techniques has been described for the non-specialist.

2 FUNDAMENTALS OF ELECTROCHEMISTRY

2.1 Definition of Standard Potential

A standard potential is defined as the *reduction potential* of a redox system under thermodynamic control according to the Stockholm convention.^{16,17} By definition, the standard reduction potential refers to standard conditions where all reactants are at 1.0 M activity or 1 atm pressure at 298 K. In dilute solutions of 1 mM, it is generally acceptable to use concentrations in place of activities. The standard reduction potential of a radical is given as the addition of an electron to an odd-electron species to yield an even-electron anion as in (1). Likewise, the oxidation potential of a radical species is the addition of an electron to an even-electron cation to generate an odd-electron species as in (2).

The equilibrium for an electron transfer reaction between two species A and B, as defined in (3) at an electrode, is described by the Nernst equation (4), where E is the applied electrode potential, E^0 is the standard potential, $[A]$ and $[B]$ are the concentrations of the redox species at the electrode surface, F is Faraday's constant equal to $96\,485\text{ C mol}^{-1}$, and n is the number of electrons transferred per mole. Thermodynamic control is obtained when both molecular species are stable and in equilibrium at the electrode interface during the course of the experiment. For such a situation, the heterogeneous electron transfer between the substrate and the electrode must be fast ($\sim 1\text{ cm s}^{-1}$) so the interface concentrations can respond to the electrode potential.

$$E = E^0 + \frac{2.303RT}{nF} \log \frac{[A]}{[B]} \quad (4)$$

Due to the transient short-lived nature of radicals, they are generally difficult to isolate. Therefore, measuring the redox potential of a radical generally involves either the oxidation of a stable anion to the radical as in (1) or the reduction of a stable cation to the radical as in (2). A common strategy has involved the deprotonation of a weak acid in the presence of an added strong base and recording the oxidation wave of the anion using cyclic voltammetry. However, this method is limited to those anions stable in the assay solution. Hence, another approach that has been discussed in greater detail involves the generation of radicals by homolytic cleavage of a covalent bond. This can be accomplished by reductive homolytic cleavage of a substrate on accepting an electron via a dissociative electron transfer reaction,^{18–22} either transferred at an electrode or by a radical-anion catalyst in solution, or by homolytic cleavage of a frangible bond on irradiation with a light source.^{23–25}

3 METHODS FOR DETERMINING THE REDOX POTENTIALS OF RADICALS

3.1 Electrochemical Techniques

3.1.1 Cyclic Voltammetry with Microelectrodes

Cyclic voltammetry is a versatile technique for the determination of pertinent thermodynamic and kinetic information of radicals.^{11,14,15} The technique involves changing the potential of the working electrode linearly from an initial potential to a switching potential and back to the starting potential position. Within this potential window between the initial and switching potential, any redox active substrate is oxidized or reduced, according to the direction of the applied potential, and recorded as a change in current. The resulting voltammogram is a plot of the detected current versus the applied potential. The forward scan initiates the heterogeneous electron transfer reaction at the electrode and the reverse scan is diagnostic for detecting redox active intermediates and products. Formation of these stable products can be revealed in the initial scan or

probed by repetitive (multicycling) scans. The time parameter, RT/Fv , is controlled by the scan rate, the rate at which the potential changes as a function of time. The advent of ultramicroelectrodes has extended the upper limit to scan rates of 1 MV s^{-1} such that intermediates with a lifetime on the order of $1 \mu\text{s}$ can be characterized.

The simplest reaction that can be monitored by cyclic voltammetry, as represented by (3), corresponds to a single-electron transfer between the electrode and substrate in which both chemical species are stable and at equilibrium during the timescale of the experiment. A typical cyclic voltammogram for a fully reversible process, as illustrated in Figure 1, is characterized by scan rate and concentration independent peak potentials with a constant peak separation of 59 mV at 25°C and a current cathodic to anodic peak ratio equal to 1. The standard potential is obtained from the midpoint of the cathodic peak potential, E_{RED} , and the anodic peak potential, E_{OX} .

While there are many examples of reversible cyclic voltammograms for the reduction and oxidation of neutral molecules to their corresponding radical anions or radical cations, there are only a limited few examples of persistent free radicals that are stable on the time scale of the voltammetry experiment.²⁶ Examples of these longer lived radicals include trimethylaryl,^{27–29} nitroxyl,^{30–32} perchlorophenalenyl,³³ dithiadiazolyl,³⁴ and verdazyl radicals.³⁵ The use of ultramicroelectrodes in voltammetry has increased the accessible time window available for the direct evaluation of radical

standard potentials. Still, in cases where equilibrium is not obtained, the direct evaluation of the redox properties by cyclic voltammetry is generally not a straightforward task and requires an understanding of the influence of the heterogeneous kinetics as well as the effect of follow-up homogeneous reaction kinetics.

3.1.2 Effect of Heterogeneous Kinetics

Many simple redox systems corresponding to (3) display irreversible voltammograms due to a slow heterogeneous electron transfer from the electrode to the substrate. Strictly speaking, thermodynamically significant standard potentials can only be directly obtained from reversible voltammograms. However, with an understanding of the effects of the heterogeneous kinetics on the observed potential measurement, determination of accurate thermodynamic information is obtainable.

Figure 2 illustrates a series of cyclic voltammograms for a simple redox system as a function of the decreasing apparent rate constants. As the kinetics of the heterogeneous electron transfer get slower, an overpotential is required to transfer the electron to the substrate. The trend one observes as the apparent kinetics get slower is a decrease in the peak current, an increase in the cathodic to anodic peak current ratio, and an increase in the peak-to-peak separation, although the midpoint between the peak currents can still provide an estimate of the standard potential.

Figure 1 Simulated cyclic voltammogram of a fully reversible one-electron redox system at 25°C with a 3-mm-radius micro-electrode.

Figure 2 Simulated cyclic voltammograms for a reversible redox system at a standard potential of zero and a heterogeneous forward rate constant k_{HET} of (a) 1, (b) 10^{-1} , (c) 10^{-2} , and $10^{-3} \text{ cm s}^{-1}$.

The peak current is dependent on the square root of the scan rate and the substrate concentration (5). Under these circumstances, the cyclic voltammogram is said to be quasi-reversible:

$$i_p = (2.69 \times 10^5) n^{3/2} A D^{1/2} C v^{1/2} \quad (5)$$

For a reduction process, the apparent heterogeneous rate constant, k_{app} , is related to the standard rate constant, k^0 , at the standard potential and an exponential component that accounts for the overpotential, $E - E^0$, and the symmetry factor, α , as given in (6). When the redox system obeys the Nernst equation and the kinetics are fast, there is no overpotential and the observed rate constant is k^0 . However, any overpotential contribution results in lowering the apparent rate constant and shifting the reduction peak to more negative potentials:

$$k_{app} = k^0 \exp\left(\frac{-\alpha n F}{RT}(E - E^0)\right) \quad (6)$$

Deviation from the Nernst equation for a reduction reaction involving species A converted to B results when the product is reluctant to accept the electron. This could be the consequence of a significant structural change between the neutral and reduced (oxidized) forms, which requires substantially more potential to overcome the intrinsic barrier, resulting in a lower k_{app} . A fast irreversible follow-up reaction after the reversible electron transfer at the electrode results in a reduction current at less extreme potentials compared to the case with no follow-up homogeneous kinetics, which acts as a positive overpotential contribution. Thus, the overpotential is mainly the contribution from the heterogeneous kinetics, but the ensuing homogeneous reactions can, in some cases, counteract the negative overpotential.

Cyclic voltammograms can also appear to have non-Nernstian peak-to-peak distances when there is a considerable ohmic drop (iR), notably in nonaqueous solutions. The potential drop is a measure of the solution resistance between the working and reference electrode. It is proportional to the current at the working electrode and the distance between the two electrodes so at higher scan rates and larger electrodes, its contribution to the applied potential can be quite substantial. If the cyclic voltammograms are not corrected for the iR contribution, the peak-to-peak separation

appears larger and the anodic and cathodic peak currents lower resulting in an error in the k^0 . For example, with a 3-mm glassy carbon (GC) electrode in acetonitrile (ACN) solution containing 0.1 M tetrabutylammonium perchlorate, the ohmic drop is about 200 Ω . Using positive feedback systems incorporated in the electronics of the potentiostat, it is possible to compensate for the majority percentage of the ohmic drop.

3.1.3 Effect of Follow-Up Homogeneous Kinetics

In addition to the rate of the heterogeneous kinetics, the applied potential at the electrode is also dependent on the rate of follow-up homogeneous reactions. Figure 3 illustrates the effect of a homogeneous chemical reaction following the initial electrochemical step.

Curve (a) represents a reversible system with no follow-up chemistry. On introduction of a slow homogeneous reaction, the current peak ratio increases until the reverse wave is no longer observed as in curve (b), and the forward peak potential is found to shift slightly to more positive potentials as compared to case (a) when there is no follow-up homogeneous kinetics. The voltammograms labeled (c) and (d) correspond to follow-up reactions with rate constants three and six orders of magnitude greater than in (b). The curves in Figure 3

Figure 3 Simulated cyclic voltammograms for a reversible redox system at a standard potential of zero and a heterogeneous forward rate constant k_{HET} of 1 cm s^{-1} (a) and followed by an unimolecular fragmentation with a rate constant of (b) 10^3 , (c) 10^6 , and (d) 10^9 s^{-1} .

exemplify a reduction process where the forward peak potential shifts to more positive potentials; in the case of an oxidation process, the peak potential shifts to more negative potentials. Voltammograms with shapes similar to curves (c) and (d) are also commonly observed when there is a follow-up reaction after dissociative reductive cleavage of a covalent bond. However, in such cases, the peak potential shifts to more negative potentials due to the overpotential required to break the covalent bond.^{18–22} The extent of the peak shifts can be used diagnostically to determine whether the follow-up reaction is first or second order. For a reduction process, the peak potential will shift positively according to (7) and (8). These equations can be used in determining the reduction potential of radicals from the oxidation of chemically generated anions. The peak potential will be of opposite sign for an oxidation process:

$$\text{First order } \frac{\partial E_p}{\partial \log(k/v)} = 29.6 \text{ mV/decade} \quad (7)$$

$$\text{Second order } \frac{\partial E_p}{\partial \log(k[\text{Ox}]/v)} = 19.7 \text{ mV/decade} \quad (8)$$

3.1.4 Cyclic Voltammetry with Ultramicroelectrodes

The ultramicroelectrode is arguably one of the most important contributions to electroanalytical chemistry in the past two decades.^{36–43} The smaller electrode dimensions, on the order of micrometers or less, provide characteristics quite different from that of conventional millimeter diameter electrodes. The several orders of magnitude difference in dimensions between conventional electrodes and ultramicroelectrodes is the source of the advantageous properties of the latter. The current generated at an ultramicroelectrode is dependent on the geometry, so that diffusion toward the electrode is radial rather than linear at microelectrodes, which results in sigmoidal rather than peak voltammograms. Planar diffusion at a large conventional electrode provides a peak voltammogram with a diffusional tail. In contrast, radial diffusion at the ultramicroelectrode gives a sigmoidal steady-state i – E response

with defined plateau currents. For a reversible system where the diffusion coefficients of both species are similar the standard potential is obtained directly from the point of inflexion of the steady-state curve analogous to the determination of the pK_a from a pH titration curve. However, a smaller k^0 causes the sigmoidal curve to be displaced toward more extreme potentials.

Ultramicroelectrodes are useful for measurements in highly resistive media (nonpolar solvents, polymers, gaseous interfaces, and supercritical fluids) and for high-speed voltammetry at scan rates over 1 MV s^{-1} . High-speed cyclic voltammetry has been redefined by ultramicroelectrodes because of the much smaller uncompensated resistance and background capacitance.^{36,37} The distortion observed with microelectrodes is caused by a large uncompensated solution resistance (R), which creates a substantial iR drop between the applied and working electrode potentials. Because of the extremely small currents employed, typically in the nA and pA range, the current density is increased making ultramicroelectrodes much less sensitive to the solution resistance and to the iR between the working and reference electrode. Even at low electrolyte concentrations, voltammetry with ultramicroelectrode is viable. The use of fast CV techniques to measure reversible oxidation and reduction potentials of radicals has extended the scan rate range from the kV s^{-1} to the MV s^{-1} range so that intermediates with lifetimes of $1 \mu\text{s}$ can be detected. The upper limit restriction on the MV s^{-1} range stems from the solution resistance and the double layer capacitance.

3.1.5 Competitive q Method

A valuable alternative to the direct investigation of the reduction characteristics of radicals in aprotic solvents is based on a competition between electron transfer and radical anion-radical coupling.⁴⁴ The technique is based on the concept of homogeneous redox catalysis.^{18,19} An aromatic donor, D, with a known standard potential, as probed by cyclic voltammetry, is electrochemically generated with a bulk electrode to yield a stable solution of the radical anion donor, $D^{\bullet-}$, under inert atmospheric conditions (9). Once an excess of the radical anion is generated, and it is confirmed to be stable, the substrate with a reducible bond, RX, is added to the solution. The radical anion transfers an electron to

the substrate to generate the anion $RX^{\bullet-}$ (10), which normally undergoes a rapid dissociation to yield the radical $R^{\bullet}$ and an anion X^- (11). The radical $R^{\bullet}$ can then react with $D^{\bullet-}$ either by an electron transfer reaction (12) or by coupling together (13). The ratio of products can be measured by linear sweep voltammetry in conjunction with digital simulation,^{45–47} by monitoring the change in current as probed with an ultramicroelectrode or rotating disk electrode^{48–50} or by isolation of the products from preparative electrolysis in conjunction with coulometry.^{51–55} The products DR^- and R^- are often protonated to yield stable products, or in some cases, may react via a nucleophilic substitution reaction with the initial substrate.⁵⁶ Historically, RX has been used to represent alkyl halides, although it is more representative of many chemical classes with a leaving group.^{18,22}

The competition between the homogeneous ET (12), and coupling between the radical anion donor and the radical (13), is defined by the dimensionless parameter q (14):

$$q = \frac{k_{ET}}{k_{ET} + k_c} \quad (14)$$

When the reduction is readily feasible with a rate constant near the diffusion-controlled limit and $k_{ET} \gg k_c$, then q is equal to 1. However, when the reduction is slow compared to the coupling reaction and $k_c \gg k_{ET}$, then q is equal to 0. The resulting q plot exhibits an S-shaped curve with q decreasing with increasing $E_{D/D^{\bullet-}}^0$. The half-wave potential is determined by interpolation among the q points against the standard potential of the various mediators, which corresponds to where $k_{ET} = k_c$ and $q = 0.5$. Obtaining an accurate estimate of the q value generally requires measuring at least five q values per radical. In this manner, the reduction potential of short-lived carbon radicals such as

alkyl,^{45,46} allyl,⁴⁸ acyl,⁴⁸ and benzyl radicals^{44,49,52} have been evaluated. Studies have shown that coupling between aromatic radical anions and alkyl and benzyl radicals is independent of the standard potential of $E_{D/D^{\bullet-}}^0$ with a rate constant of $1 \times 10^9 \text{ M}^{-1} \text{ s}^{-1}$.^{57–59} Equation (14) provides a way of evaluating k_{ET} once q is known. The technique was first applied to alkyl halides, anhydrides, and acid chlorides substrates,^{45–49} and has also been applicable to peroxides with alkoxy radicals that undergo a rapid β -scission fragmentation,⁵² and alternatively based on hydrogen abstraction of aldehydes.⁵⁵

When the electron transfer between the radical anion donor and the radical is an outer-sphere electron transfer, the rate constant is described according to the quadratic-activation relationship given by the Marcus theory accounting for diffusion as in (15)⁶⁰:

$$k_{ET} = \frac{k_d}{1 + \frac{k_d}{K_d Z} \exp \left[\frac{\lambda}{4RT} \left(1 + \frac{\Delta G_{ET}}{\lambda} \right)^2 \right] + \exp \left(\frac{\Delta G_{ET}}{RT} \right)} \quad (15)$$

where k_d is the diffusion-limited rate constant, K_d is the equilibrium constant for formation of the encounter complex, Z is the collision frequency for an adiabatic ET, λ is the reorganization energy and ΔG_{ET} is the free energy of the ET reaction (16). Substitution of (15) into (14) yields an expression relating the q parameter as a function of $E_{D/D^{\bullet-}}^0$ as described by (17)^{61–63}:

$$\Delta G_{ET} = 23.06(E_{D/D^{\bullet-}}^0 - E_{R^{\bullet}/R^-}^0) \quad (16)$$

$$q = \frac{1}{1 + \frac{k_c}{k_d} \left\{ 1 + \frac{k_d}{K_d Z} \exp \left[\frac{\lambda}{4RT} \left(1 + \frac{\Delta G_{ET}}{\lambda} \right)^2 \right] + \exp \left(\frac{\Delta G_{ET}}{RT} \right) \right\}} \quad (17)$$

Nonlinear regression analysis with the assistance of graphing software, such as Kaleidagraph or Sigmaplot, provides a measure of the standard potential and the reorganization energy of the radical. The half-wave potential is reasonably precise

Figure 4 Competition parameter q plot for the benzyl radical as a function of the aromatic donor $E_{D/D^{\bullet-}}^0$ in DMF/0.10 M TEAP solution. [Reproduced from Ref. 52. © Royal Society of Chemistry, 2003.]

within 50 mV, whereas the estimation of the standard reduction potential has a greater uncertainty of 150 mV due to the error in estimating λ . Typical values in aprotic solvents are $k_c = 1 \times 10^9 \text{ M}^{-1} \text{ s}^{-1}$, $Z = 3 \times 10^{11} \text{ M}^{-1} \text{ s}^{-1}$, $K_d = 1 \text{ M}^{-1}$, and $k_d = 2 \times 10^{10} \text{ M}^{-1} \text{ s}^{-1}$. Figure 4 illustrates a representative set of data obtained for the benzyl radical and the fitted curve using (16) and (17).

While most q parameter studies applied linear sweep voltammetry, the use of a rotating disk electrode or ultramicroelectrode is advantageously more accurate even with slower reactions with a rate constant as low as $10^{-3} \text{ M}^{-1} \text{ s}^{-1}$.⁵¹ However, this is at the expense of having a thorough understanding of the reaction mechanism and a stable radical anion compared to those employed in linear sweep or chronoamperometry. Measurements in dimethylsulfoxide (DMSO) and *N,N*-dimethylformamide (DMF) tend to be more accurate and reproducible due to the greater solubility of oxygen and faster rate of solvent evaporation in ACN.⁵²

3.1.6 Second Harmonic Alternating Current Voltammetry

SHV is a technique that involves a direct current (DC) sweep applied at a working electrode as in CV and also involves a small 10-mV alternating current (AC) superimposed on the faradaic current.^{64–73} The frequency of the sinusoidal AC is the time parameter. The output is the current at a specific phase relative to the AC potential signal versus the DC potential. The selective detection of the

AC using a lock-in amplifier provides faradaic information, while simultaneously eliminating the double-layer charging current at the electrode. For a reversible system, a compressed symmetrical sine wave is observed and the standard potential is taken as the midpoint of the sine wave. No double-layer nonfaradaic current is observed as in cyclic voltammetry with microelectrodes.

The historic limitation with cyclic voltammetry was the restriction caused by the double-layer charging current at high scan rates. In some cases, CV can be used to outrun the follow-up chemistry, but it comes at the expense of introducing a larger double-layer charging current making it difficult to distinguish the faradaic current of the substrate from the double layer capacitance. Hence, the SHV method once provided a powerful technique for studying electrochemical reactions with fast follow-up chemistry. Nowadays, the combination of cyclic voltammetry with ultramicroelectrodes has tended to replace the utility of this unappreciated technique in the modern laboratory partly due to the complexity of data collection and analysis in SHV experiments.

3.2 Photoelectrochemical Techniques

3.2.1 Laser Flash Electron Photoinjection

This photoelectrochemical approach consists of using a short laser pulse approaching 10^{-9} s^{-1} from an excimer laser with an intensity of $20\text{--}200 \text{ kW cm}^{-2}$ to inject electrons into the electrolyte solution by irradiating a metal electrode.^{74–83} The wavelength is carefully selected in a range where the substrate absorption is weak to prevent direct photochemistry. The result is a source of low-energy electrons, typically on the order of 1–5 eV, about the electrode surface at a mean distance of 60 Å. In the absence of any substrate, the electrons return to the electrode by diffusion with no change in net charge. Pioneering work was done in aqueous solution at a mercury electrode with alkyl,^{74,75} and hydroxyalkyl radicals,^{75,76} but has been extended to methylaryl radicals.^{77–80} Compared to pulse radiolysis, where solvated electrons are generated in addition to hydrogen atoms and hydroxyl atoms (among other species), an advantage of this technique is that it allows for much

better reaction control. The technique has been applied in various organic aprotic solvents with photoelectrode materials other than mercury,^{77,78} which tends to react by absorption with radicals, and as a tool for understanding the dynamics of proton transfer reactions to carbanions.^{81,82}

In the presence of a substrate with a reducible fragile bond, the solvated electron generates a radical and an anion. Alternatively, the radical can be generated indirectly by hydrogen abstract in the presence of hydroxyl radicals generated from a solution of saturated N₂O. The net result, either way, is a thin layer of radicals on the order of 30- to 100-Å thick with a surface concentration of 10⁻¹³ mol cm⁻² at the electrode surface. Any solvated electrons that remain uncaptured by the substrate are taken up by the electrode. The time window ranges approximately from 1 μs to 1 ms. Monitoring of the photogenerated charge as a function of the DC potential applied to the working electrode yields a scattering of points along an S-shaped current-potential trajectory (photopolarograms) characterizing the reduction of the radical intermediate. At an applied electrode potential lower than the reduction potential of the radical, the radical is reduced to the anion and the net current corresponds to a count of two electrons per molecule. However, when the electrode potential is much higher than the radical reduction potential, the net current equates to one electron per molecule. The point of inflexion between the foot and plateau of the curves is the half-wave potential, which is an estimated measure of the reducibility of the radical.

The true meaning of the half-wave potentials requires an understanding of the reduction mechanism, which involves the initial electron transfer step to generate the radical, the following reduction to the anion, as well as the various homogeneous reactions the radical and anions may undergo. The Paris group has tackled these issues, including adsorption at the electrode, and derived a theoretical framework for extracting thermodynamic and kinetic parameters under a number of mechanistic situations.⁸³ In the simplest case, when the radical is stable and obeys a Nernstian electron transfer, the half-wave potential is equivalent to the standard potential, but this is not the norm due to the short-lived nature of radicals. For example, where the radical and anion are stable, but the kinetics are slow and irreversible, the half-wave potential varies linearly with the logarithmic analysis equal to

59.2 mV divided by the transfer coefficient at 25 °C, thus allowing the determination of the transfer coefficient from the radical polarogram as a function of time. From (18) and knowledge of the diffusion coefficient, *D*, the standard rate constant, *k_s*, and the time parameter, *t*, the standard potential *E*⁰ can be determined. Other mechanistic scenarios including fast first- and second-order follow-up reactions and adsorption of the radical onto the electrode surface are also theoretically examined in detail⁸³:

$$E_{1/2} = E^0 + 0.2626 \frac{RT}{\alpha F} + \frac{RT}{\alpha F} \ln \left(k_s \sqrt{\frac{t}{D}} \right) \quad (18)$$

3.2.2 Photomodulation Voltammetry

Photomodulated voltammetry was developed by Wayner, Griller, and coworkers at the Steacie Institute in Ottawa.⁸⁴⁻⁹⁴ Recent studies on the redox properties of radicals by this technique have been published by the Danish team in Aarhus⁹⁵⁻⁹⁸ and the Austrian team in Graz.^{99,100} The method involves the photolysis of a labile substrate with modulated light to generate the radical and combines an electrochemical technique to study and characterize the reactive intermediate. Based on the principles of flash photolysis, the radicals are generated continuously in a flow cell by photolysis of the substrate. Two general approaches, one direct and the other indirect, allows for flexibility in the choice of substrate. The first approach is based on photodecomposition of a suitable precursor. Common examples include ketones, which decompose via α-cleavage of a C–C (19) or alkyl halides that decompose via R–X cleavage to yield R[•] directly (20). A second approach involves the photolysis of an organic peroxide, such as di-*tert*-butyl peroxide, which undergoes homolytic cleavage of the O–O bond to yield *tert*-butoxyl radicals (21), which subsequently abstract a hydrogen atom from the parent compound to generate the R[•] species of interest (22). Generation of an alkoxyl radical capable of rapid β-cleavage to yield a ketone and a radical provides an alternative strategy via (23):

Photolysis is accomplished using a high-power Hg-Xe lamp in an electrochemical cell with a quartz window and a gold mini-grid (or carbon net) working electrode sandwiched between two quartz windows. Modulation of the light is controlled sinusoidally by a mechanical chopper that blocks the light with a specific frequency, which causes the concentration of radicals to oscillate at a fixed frequency. The oscillation produces a small AC up to 500 nA at the same frequency as the lamp. Detection is accomplished with a lock-in amplifier. The technique can be used to detect radicals with lifetimes in the order of 1 ms at concentrations as low as 10^{-7} M, where second-order homogeneous processes are not a mechanistic issue.

The $E_{1/2(\text{R}^\bullet/\text{R}^-)}$ and $E_{1/2(\text{R}^\bullet/\text{R}^+)}$ are determined directly from the points of inflexion of the steady-state voltammograms recorded as plots of the AC versus the electrode potential. Frequently, these half-wave potential provide a reliable estimate of the standard potentials, at times accurate to within 50 mV of the standard reduction potential. However, exceptions are common place as the current is controlled not only by diffusion but also by the heterogeneous kinetics and as well as homogeneous reactions of the species involved as previously discussed.

3.3 Pulse Radiolysis

Pulse radiolysis is a widely used technique for studying the thermodynamic properties of radicals in aqueous media.^{101–110} Radicals are generated using short pulses of high-energy electrons of up to 20 MeV. The source of the irradiation can be particulate matter (electrons and α -particles) or photonic (X-rays, γ -rays, and high-intensity UV laser light). The radiolysis of water is initiated by the excitation and ionization of the solvent resulting in the formation of a number of reactive intermediates, the three most significant species are a hydroxyl radical $\text{OH}^\bullet$, a hydrated

electron e_{aq}^- , and a hydrogen atom $\text{H}^\bullet$ (24) (see **Radiation-Induced Radical Reactions**):

In the presence of a substrate, these three species give rise to various secondary reactive intermediates. The technique is not limited to aqueous solutions; however, most organic solvents are generally not suitable due to poor absorptivity properties of the solvents and/or competing chemical side reactions. Detection methods for the characteristics of the radicals include both optical and electrochemical methods. Commonly used optical techniques include UV–Visible absorption spectroscopy, Rayleigh scattering, and resonance Raman spectroscopy, while common electrochemical methods employed include conductivity, electron paramagnetic resonance, or polarography.

A drawback of the pulse radiolysis technique is poor selectivity. Hydrogen atoms and electrons are strong reductants as well as capable of hydrogen abstraction and alkene addition, while hydroxyl radicals are a powerful oxidant. To circumvent many of these undesirable reactions, various scavengers, such as N_2O , $\text{S}_2\text{O}_8^{2-}$, N_3^- , Br^- , and 2-methyl-2-propanol, are used to manipulate the reactivity conditions in order to obtain conditions supporting the desired radical. Another limitation of the pulse radiolysis technique is the specialized nature of the equipment, which tends to prevent most research groups from easy access to the instrumentation. A compilation of radical standard potentials in water were presented by Wardman in 1989.¹⁰¹

3.4 Thermochemical Cycles

Thermochemical cycles provide a way of obtaining the redox potential of radicals from existing thermodynamic data and group additivity tables.^{111–115} A commonly used scheme includes the $\text{p}K_{\text{a}}$ of the corresponding RH compound, the bond dissociation energy of the RH bond, and the known standard potential of the hydrogen atom. This relationship between the $\text{p}K_{\text{a}}$, the bond dissociation free energy, ΔG_{BDE}^0 , and the standard potential of the radical, $E_{\text{R}^\bullet/\text{R}^-}^0$, is given in Scheme 1 and summarized in (25). The $E_{\text{H}^+/\text{H}^-}^0$ in various solvents is known—for DMF, the value is -2.45 V versus the normal hydrogen electrode (NHE). A detailed review of the

Scheme 1 Thermodynamic cycle for the relationship between the bond dissociation energy, acid dissociation constant, and the standard potentials of a hydrogen atom and a corresponding radical.

Scheme 2 Thermochemical cycle for relating the gas phase ionization potential to solution standard potential.

approach is given by Wayner and Parker^{8,115}:

$$2.303RT\text{p}K_{\text{a}} = \Delta G_{\text{BDE}}^0 + F(E_{\text{H}^+/\text{H}^\bullet}^0 - E_{\text{R}^\bullet/\text{R}^-}^0) \quad (25)$$

3.5 Computational Electrochemistry

With the ever increasing performance in computer processing technology and the continuing increase in experimental free radical data, the time has come to accept computational electrochemistry as mainstream. Many research groups have developed theoretical approaches for predicting the standard redox potentials of radicals in different solutions.^{116–121} The general approach is to employ a theoretical method to correlate gas-phase ionization energies and then calibrated with a solvation model for the solution phase to calculate standard reduction potentials as shown in Scheme 2. Despite the improved reliability in the methods employed, these calculations still come with some assumptions, yet many authors claim to obtain reliable results with high levels of precision. Schmittl *et al.*,¹¹⁶ for example, have recently reported the experimental oxidation potentials of over 40 select enols, enolates, and α -carbonyl radicals and linearly correlated the computed ionization potentials after correcting for solvation. Perhaps the most comprehensive study to date calculated the standard redox potential of over

270 carbon-centered free radicals in ACN to derive a calibrated linear correlation with a precision of 0.2 V.¹¹⁷ The study was limited to compounds with less than 13 nonhydrogen atoms and only for one-electron processes. The one-electron reduction potentials for a range of oxygen- and sulfur-centered radicals in protic and aprotic solvents have also been demonstrated in both protic and aprotic solvents.¹¹⁸

4 TABLES OF REDUCTION, OXIDATION, AND STANDARD POTENTIALS

The reduction $E_{1/2}(\text{R}^\bullet/\text{R}^-)$ and standard potentials $E^0(\text{R}^\bullet/\text{R}^-)$ of the radicals are reported in Table 1 and the oxidation potentials $E_{1/2}(\text{R}^\bullet/\text{R}^+)$ and standard potentials are reported in Table 2. In aqueous solution, the measurement of standard potentials is universally made with respect to the NHE with all components at unit activity in water and defined as the *international accepted zero potential*. As pulse radiolysis experiments are customarily performed in aqueous solution, standard potentials obtained with this technique are reported versus NHE. However, in most cases, electrochemical measurements of many organic substrates are impractical in water, often due to insolubility or instability. Hence, the convention adopted by most laboratories working in nonaqueous solutions is to report experimentally determined potentials versus the saturated calomel electrode (SCE) with respect to a

reference or pseudo reference electrode such as a silver wire. The recommended convention is to report potentials obtained in different solvents using the ferrocenium/ferrocene redox system as an internal standard.^{16,17} This approach allows for the quantitative comparison of standard potentials measured in over 20 various nonaqueous solvents. Because of the popularity of referencing versus SCE, the potentials in Tables 1 and 2 are with respect to this reference. It is worth noting that comparisons of potentials from various literature resources should only be compared against or related to the same reference electrode, otherwise an associated error will be included. The silver–silver chloride electrode is another commonly used reference electrode, which has a potential of 0.197 V versus NHE. Conversion of the tabulated SCE values in Tables 1 and 2 to NHE requires the subtraction of 0.242 V.

Converting from one reference electrode to another, admittedly, introduces an uncertainty error in the measured standard potential. However, the greatest source of error results from the indiscriminate use of irreversible peak potentials as a substitute for the standard potentials when there is a large overpotential either from cleavage of a bond or from some other major structural organization within the substrate. This sort of error can be in excess of 1 V. A number of other parameters also introduce uncertainty and it is always advisable to compare potentials measured with the same solvent, working electrode, electrolyte, and electrolyte concentration. Comparisons of potentials are most accurate when referred to the same reference electrode—such a mix up can easily introduce an error in the order of 0.3 V.^{122,123} In contrast, errors associated with using values from different inert electrodes are generally not severe with typical discrepancies in the order of 0.10 V, but larger inconsistencies in the order of 0.25 V have been observed.⁷⁷ Discrepancies resulting from potentials measured in various organic solvents and electrolytes are also generally limited to errors of 0.10 V. For example, the following documented corrections highlight this point: DMF (0.480 V vs SCE), ACN (0.410 V vs SCE), and DMSO (0.430 V vs SCE).¹³

The redox potentials in Tables 1 and 2 have been mainly limited to those measured in ACN, DMF, DMSO, and aqueous (W) solutions. This restriction

is based on practicality since the largest collection of data is reported in nonaqueous polar solvents, although for biological applications redox potentials in aqueous solution are, of course, the ideal. Measurements are typically made with either GC, mercury (Hg), platinum (Pt), or gold (Au) electrodes. Mercury with its long tradition as an electrode material is often chemically involved in the reaction even in the cases where no stable mercury products are detected. As an electrode, mercury often behaves as a heterogeneous inner-sphere, rather than outer-sphere, electron donor in the reduction reactions. Gold and platinum have demonstrated to be inert for most substrates, although they are known to act as electrocatalysts under certain circumstances. Even GC with a reputation as an inert, outer-sphere electron transfer material is susceptible to reactivity with certain radicals, such as with the phenyl radical, which forms a thin layer and insulates the electrode.¹²⁴ From this perspective, it is advisable to measure the redox properties of radicals by electrochemical means using multiple types of electrode materials and techniques. This concern is reflected in Tables 1 and 2.

Tables 1 and 2 each contain eight columns. In column 1, the name of the radical is given, and in column 2, the molecular formula is provided for the simpler radicals. They are listed in general order of the number of carbon atoms, further subgrouped according to the nature of the radical centre: carbon, oxygen,¹²⁵ nitrogen,¹²⁶ sulfur,¹²⁷ other group IV elements,⁹⁵ and selenium.⁹⁶ Column 3 contains either the half-wave reduction or half-wave oxidation potentials and column 4 the thermodynamic standard potential. Columns 5 and 6 describe the experimental conditions, the electrode material in the case of electrochemical detection, and the solution/electrolyte solution, respectively. The various electrochemical and photoelectrochemical techniques used to measure the redox properties of each radical are listed in column 7 and the primary literature reference is provided in column 8. When the data are available, a number of standard potentials for the same radical species are included in the tables to allow for an appreciation for the differences associated with different experimental techniques and conditions from various laboratories.

Table 1 Reduction and standard potentials of radicals.

Radical	Structure	$E_{1/2}(\text{R}^{\bullet}/\text{R}^{-})$ vs SCE	$E^0(\text{R}^{\bullet}/\text{R}^{-})$ vs SCE	Electrode material	Solvent	Techniques	Reference

Table 2 (continued)

Radical	Structure	$E_{1/2}(R^+/R^+)$ vs SCE	$E^0(R^+/R^-)$ vs SCE	Electrode material	Solvent	Techniques	Reference
<i>t</i> BuNO [•] PhRtBu	R = 2- CO ₂ CH ₃		0.90	GC	ACN (0.1 M TBAB)	CV	135
	R = 2- CO ₂ ⁻ K ⁺		0.33	GC	ACN (0.1 M TBAB)	CV	135
Perchlorophenalenyl	[•] C ₁₃ Cl ₉	0.97		Pt	ACN (0.1 M TBAH)	CV	33
Nitrogen-centered radicals							
Verdazyl	[•] NNR ₁ CON R ₂ N=CR ₃						
	Ph, Ph, Ph		0.85	GC	ACN (0.1 M TBAB)	CV	35
	CH ₃ CH ₃ Ph		0.68	GC	ACN (0.1 M TBAB)	CV	35
	<i>i</i> Pr, <i>i</i> Pr, Ph		0.59	GC	ACN (0.1 M TBAB)	CV	35
	<i>i</i> Pr, <i>i</i> Pr, 2-pyridyl		0.61	GC	ACN (0.1 M TBAB)	CV	35
	<i>i</i> Pr, <i>i</i> Pr, 2-imidazolyl		0.65	GC	ACN (0.1 M TBAB)	CV	35
	<i>i</i> Pr, <i>i</i> Pr, <i>N</i> -methyl-2-imidazolyl		0.64	GC	ACN (0.1 M TBAB)	CV	35
Verdazyl, methylene	[•] NNR ₁ CH ₂ N R ₂ N=CR ₃						
	H, H, H		0.19	GC	ACN (0.1 M TBAB)	CV	35
	OCH ₃ , OCH ₃ , OCH ₃		0.02	GC	ACN (0.1 M TBAB)	CV	35
	CH ₃ CH ₃ CH ₃		0.10	GC	ACN (0.1 M TBAB)	CV	35
	H, H, CH ₃		0.17	GC	ACN (0.1 M TBAB)	CV	35
	Cl, Cl, CH ₃		0.26	GC	ACN (0.1 M TBAB)	CV	35
	CH ₃ CH ₃ OCH ₃		0.11	GC	ACN (0.1 M TBAB)	CV	35
	CH ₃ CH ₃ H		0.12	GC	ACN (0.1 M TBAB)	CV	35
	CH ₃ CH ₃ Cl		0.15	GC	ACN (0.1 M TBAB)	CV	35
Sulfur and selenium-centered radicals							
Acetylthiyl	[•] SC(O)CH ₃		0.98		W, pH > 8	PR	109
Hydroxyethanethiyl	[•] SCH ₂ CH ₂ OH	-0.36		Pt	ACN (0.1 M TBAP)	CV	136
Phenylthiyl	[•] SC ₆ H ₄ X						
	4-NH ₂	0.35		Au	ACN (0.1 M TBAB)	PM	97
	4-OCH ₃	0.68		Au	ACN (0.1 M TBAB)	PM	97
	4-CH ₃	0.68	-0.035	Au	ACN (0.1 M TBAB)	PM	97
	4-F	0.79	0.040	Au	ACN (0.1 M TBAB)	PM	97
	4-H	0.79		Au	ACN (0.1 M TBAB)	PM	97
	4-Cl	0.90	0.07	Au	ACN (0.1 M TBAB)	PM	97
	4-Cl	0.62	0.180	Pt	ACN (0.1 M TBAP)	CV	136
	4-C(O)OCH ₃	0.86		Au	ACN (0.1 M TBAB)	PM	88
	4-CN	0.98		Au	ACN (0.1 M TBAB)	PM	88
	4-NO ₂		0.455	Pt	ACN (0.1 M TBAP)	CV	136
Phenylselanyl	[•] SeC ₆ H ₄ X						
	N(CH ₃) ₂	0.27		C	ACN (0.1 M TBAB)	PM	96
	OCH ₃	0.61		C	ACN (0.1 M TBAB)	PM	96
	CH ₃	0.62		C	ACN (0.1 M TBAB)	PM	96
	F	0.70		C	ACN (0.1 M TBAB)	PM	96
	H	0.70		C	ACN (0.1 M TBAB)	PM	96
	Cl	0.73		C	ACN (0.1 M TBAB)	PM	96
	Br	0.74		C	ACN (0.1 M TBAB)	PM	96
	CN	0.82		C	ACN (0.1 M TBAB)	PM	96
Silicon and tin-centered radicals							
Triphenylsilyl	[•] SiPh ₃	-0.41		Au	ACN (0.1 M TBAP)	CV	95
Tributylstannyl	[•] SnBu ₃	0.20		Au	ACN (0.1 M TBAP)	CV	95

C, carbon; GC, glassy carbon; Au, gold; Pt, platinum; ACN, acetonitrile; DMF, *N,N'*-dimethylformamide; DMSO, dimethylsulfoxide; W, water; TBAB, tetrabutylammonium fluoroborate; TBAP, tetrabutylammonium perchlorate; TBAH, tetrabutylammonium hexafluorophosphate; CV, cyclic voltammetry with microelectrode; SHV, second harmonic AC voltammetry; PR, pulse radiolysis; PM, photomodulation voltammetry.

Overview of Radical Initiation

Jacques Lalevée and Jean Pierre Fouassier

Département de Photochimie Générale, CNRS, Université de Haute Alsace, Ecole Nationale Supérieure de Chimie de Mulhouse (ENSCMu), Mulhouse, France

1 INTRODUCTION

Different fields of chemistry require efficient and convenient methods for the generation of radicals that can be further used as initiating species in various chemical reactions. Radical initiators (RIs) can thus be considered as compounds that can produce free radicals under mild conditions to promote radical reactions. Many chemical approaches using free radical chemistry, as exemplified in the growing number of applications, have been developed for organic synthesis purposes; see also Volume 2 of this encyclopedia.^{1–5} Free radical polymerization reactions are also strongly affected by the nature of the initiators^{6,7} and some selected properties such as the control of the polymerization^{8,9} can be tuned by a careful choice of the initiating system; see also Volume 4 of this encyclopedia. Radicals are also involved in many important biological processes and a clean generation of these intermediates is often required for a better understanding of the associated mechanisms.^{10–20}

The generation of a radical can occur through several routes. The first one is referred to as homolysis and it requires RIs with relatively weak covalent bonds. The activation energy is provided by

1. heating (this is the most classical way),
2. light absorption (this is highly worthwhile for compounds bearing a suitable chromophore),
3. radiolysis (X-ray, γ irradiation, etc.) or sonolysis (these two approaches are not often used).

The second route where radicals are formed by redox reactions is very different. In such processes, an electron is transferred to (or from) a molecule possessing paired electrons, thereby generating a radical anion (or a radical cation); the fragmentation of this latter species leads to a radical and an anion (or a cation). Other routes are also employed: for example, the direct oxidation (or reduction) of an anion (or a cation) by electrochemical methods leading to the formation of a radical. The use of readily oxidizable compounds (e.g., organoboranes) that generate carbon-centered radicals in the presence of molecular oxygen has also been reported (see **Boron in Radical Chemistry**). This latter approach is very useful for low temperature experiments.

Owing to the broad area of free radical chemistry, many reviews or books are already available in the literature.^{1–20} In this article, representative RIs are described according to their different generation pathways. A detailed description of the application of these initiators in radical chemistry is provided in the other articles of this encyclopedia.

2 THERMOLYSIS

Thermolysis of an RI relates to a single bond cleavage upon heating. To operate at a temperature below 150 °C, the RI must not exhibit a dissociation energy exceeding 40 kcal mol^{–1}. This corresponds to a severe criterion for thermal initiators. Indeed, as

Table 1 Bond dissociation energies of representative single bonds.²¹

Single bonds	BDE (kcal mol ⁻¹)
CH₃-H	105
CH₃-CH₃	90.2
PhC(O)-OCH₃	97.9
(CH₃)₂CH-I	56.1
PhS-SPh	51.2

CF₃O-OCF₃	47.5

The chemical bond is given by the bold atoms.

shown in Table 1 where some typical representative data for the bond dissociation energy (BDE) of various typical single bonds are provided, it is clearly noted that C–C bonds are usually too strong for thermolysis. Obviously, BDEs are dramatically affected by the substituents so that these data can only be used as a general trend. Therefore, the functional groups that could fit the energy requirement are mainly based on heteroatom–heteroatom or carbon–heteroatom bonds such as in peroxides,

azo compounds, nitrite esters, halogen molecules, *N*-hydroxy-pyridine-2 thione esters, and so on.

RI, as a function of their structure (especially organic peroxides and azo compounds), might be inherently unstable. They are generally stored in a refrigerator and care should be taken while handling these compounds. A good compromise must be achieved for RIs: they must be stable at room temperature but should decompose under mild conditions to generate the targeted radicals.

2.1 Peroxides

The generation of radicals through thermolysis of peroxides has been used for a long time. The RO–OR bond is relatively weak, with a BDE of 35–50 kcal mol⁻¹ depending on the R substituents. This is less than half of the bond strength of the usual C–C, C–H, and C–O bonds (Table 1). The RO–OR bond easily breaks and forms alkoxy radicals (RO[•]):

**Table 2** Decomposition rates (k_d in s⁻¹) and 10 hours half-life temperatures for typical commercial peroxides in benzene (except otherwise noted).^{6,7}

Scheme 1 Decomposition of benzoylperoxide.

A large number of chemical compounds of this type are commercially available. In fact, these structures belong to the most widely used initiators in free radical polymerization (see **Radical Polymerization in Industry**). Representative parameters (half-life temperature and decomposition rate) characterizing the bond cleavage process are gathered in Table 2. As can be seen from the table, there are initiators for basically any temperature regime. To ensure good radical production, a proper initiator has to be chosen in the experiment.

In diacylperoxides (RC(O)OOC(O)R), the formation of acyloxyl radicals is usually followed by a decarboxylation reaction (Scheme 1). These peroxides exhibit lower BDE(O–O) than most dialkylperoxides. This is related to the acyloxyl radicals that are stabilized by resonance, the unpaired electron being delocalized over both oxygen atoms. In diacylperoxides, the substituents have a rather low effect on the decomposition rate constants (Table 2); that is, benzoylperoxide and lauroyl peroxide (which are two of the most commonly employed diacylperoxides) exhibit quite similar decomposition parameters.

Some fast fragmentations for oxyl radicals can be observed (depending on their structures) because of the formation of a stable ketone; that is, for *t*BuO[•], fragmentation leads to a methyl radical (CH₃[•]) and acetone (Scheme 2). A similar process is also observed for cumyloxyl fragmentation (Scheme 2).^{10–16,22}

Scheme 2 Fragmentation processes for *t*BuO[•] and PhC(CH₃)₂O[•].

2.2 Azo Compounds

Azo compounds R–N=N–R act as precursors for different carbon-centered radicals (R[•]) and release N₂ upon heating (or by irradiation—see below). The formation of N₂ (characterized by a very strong triple bond) is the driving force for this cleavage process. The decomposition rate constant is strongly affected by the substituent (R) as this R-group can strongly stabilize the generated radical, thereby enhancing the efficiency of the dissociation process (Table 3). These compounds are widely used (among them, 2,2'-azobisisobutyronitrile, AIBN) to generate radicals under mild conditions both in organic synthesis and polymer science. For example, AIBN yields isobutyronitrile radicals (Scheme 3).

Scheme 3 Decomposition mechanism of 2,2'-azobisisobutyronitrile.

Table 3 Ten hours half-life temperature and decomposition rates (*k_d*) for typical commercial azo compounds.^{6,7}

Azo compounds	<i>k_d</i> (s ^{−1}) (<i>T</i> , °C)	<i>T</i> for 10 h half-life (°C)
2,2'-Azobisisobutyronitrile	2.2 × 10 ^{−6} (50)	65 ^a

4,4-Azobis(4-cyanovaleic acid)	1.9 × 10 ^{−5} (69) ^b	69 ^b
2,2'-Azobis(2-methylpropionamidine)dihydrochloride	—	56 ^b

^a In toluene.

^b In water.

Unsymmetrical azo compounds obviously form two different radicals. Owing to in-cage recombination of the generated radicals, the amount of liberated radicals that are ready for chain initiation is far below the theoretical yield (for further discussion on that issue, see Section 2.6 of this article).

2.3 Initiators for Radical Chain Processes

Radical chain reactions are, meanwhile, frequently used as key steps in organic synthesis.^{1–5,23–26} A detailed description of these reactions is beyond the scope of this article and will be presented in other articles of this encyclopedia devoted to applications in chemical synthesis (see Volume 2).

The radicals generated by thermolysis of peroxides (see Section 2.1) or azo compounds (see Section 2.2) can act as initiating radicals ($\text{In}^\bullet$) for such radical chain processes. A hydrogen abstraction reaction between $\text{In}^\bullet$ and a given H-donor (R-H) that can start the radical chain reaction after H-transfer is required in a primary step as shown in reaction (3) for the reduction of an alkyl halide (R'-X) to the corresponding hydrocarbon (R'-H) (see reactions 4 and 5). The R-H compound must exhibit good hydrogen transfer properties to ensure an efficient reduction step.²⁷

Other useful synthetic reactions (cyclizations, reductions of xanthate, C–C bond formations, hydrosilylations, etc.) can also be conducted by radical chain processes (see **Xanthates and Related Derivatives as Radical Precursors**, **Silanes as Reducing Reagents in Radical Chemistry**, and **Radical Cascade Reactions**).

Tributyltin hydride is probably the most widely used reducing reagent R-H for conducting radical chain reactions (see **Tin Hydrides and Functional Group Transformations**). However, owing to the toxicity of this tin derivative, various promising radical chain reducing reagents have been

reported.^{28–31} Among them, silicon hydrides or germanium-based compounds appeared as the most interesting, for example, the popular tris(trimethylsilyl)silane, TTMSS (for an in-depth discussion, see **Silanes as Reducing Reagents in Radical Chemistry**). More recently, *N*-heterocyclic carbene–borane complexes were also proposed as tin hydride substitutes.^{32,33} Many kinetic parameters associated with the reduction process are available. For example, the rate constants for reaction (3) with $\text{In}^\bullet = t\text{BuO}^\bullet$ are available at room temperature for different H-donors (see part—hydrogen abstraction reaction).^{33–36}

2.4 Other Heteroatom–Heteroatom or Carbon–Metal Bond Containing Radical Initiators

As mentioned above, the C–C single bond is typically too strong for thermolysis (e.g., 90.2 kcal mol^{−1} for ethane; see Table 1). However, with appropriate substituents, some C–C bonds become susceptible to be cleaved thermally. This can be achieved by installing phenyl groups as substituents. For example, C-radicals can be easily generated by thermolysis of diphenyl(4-triphenylmethyl-2,5-cyclohexadien-1-ylidene)methane ($k_d \sim 3 \times 10^{-3} \text{ s}^{-1}$ at 273 K).³⁷ However, such a cleavage process is only efficient if highly stabilized C-radicals are generated. Therefore, most initiators operate by heteroatom–heteroatom or carbon–metal bond cleavage. In addition to peroxides and azo compounds (as discussed above), some other substance classes have found application as initiators, as discussed below.²⁰

2.4.1 Hydrazine Derivatives

Albeit the N–N bond in $\text{R}_2\text{N-NR}_2$ compounds ($\text{R} = \text{alkyl or H}$) is relatively strong, the BDEs of adequately substituted hydrazines are substantially reduced, allowing them to be used as RIs. For example, through the introduction of phenyl groups, tetraphenylhydrazine becomes an efficient precursor of diphenyl aminyl radicals.³⁸ The rate constant for the thermal decay of tetraphenylhydrazine is about $2 \times 10^{-4} \text{ s}^{-1}$ at 350 K in 1,2-dichlorobenzene:

2.4.2 Nitrites and Nitrates (N–O Bond)

The thermolysis of the N–O bond of alkylnitrites and alkylnitrates has been intensively investigated. These compounds exhibit low N–O BDEs ($\sim 37 \text{ kcal mol}^{-1}$) and can generate alkoxyl radicals upon heating. Data on gas phase kinetics are available in the literature.^{39,40} The thermolysis of O-phenyl oxime ethers (through N–O cleavage) was reported as a route to iminyl radicals.⁴¹

Nitrosothiols or nitroso-*N*-acylamines are characterized by weak S–N or N–N bonds, respectively. In analogy to alkylnitrites, these compounds generate $\text{}^\bullet\text{NO}$ upon heating:

2.4.3 *N*-hydroxypyridine-2-thione esters (N–O Bond)

Various *N*-hydroxypyridine-2-thione esters have been applied as sources of carbon-centered radicals.⁴² However, they are generally decomposed by photolysis as they exhibit very suitable light absorption spectra covering the emission spectra of usual UV–visible lamps (i.e., Hg or Hg–Xe or Xe lamp). A more detailed description of the photochemical processes involved is given in Section 4 of this article.

2.4.4 Disulfides (S–S Bond)

The RS–SR' bond is relatively weak (particularly for R=Ar; Table 1) and can be cleaved by heating (reaction 10). The bond strength is strongly affected by the nature of the R/R' substituents. For symmetrical disulfides, only one type of radical is generated (2 equiv of the same thiyl radical).

For *p*-tolyl disulfide or 2,2'-dithiobisbenzothiazole, typical decomposition rate constants lie

in the range of $8 \times 10^{-6} - 2 \times 10^{-8} \text{ s}^{-1}$ at 350 K.⁴³ Under photolysis, a similar S–S bond cleavage process occurs (see Section 4).

2.4.5 Organometallic Compounds (M–C Bond)

Some organometallic compounds are characterized by relatively weak metal carbon (M–C) bonds. Clean free radical formation is observed for XR_4 or XR_2 (with X = Sn or Hg and R = alkyl for example). However, these reactions mainly occur in the gas phase at a relatively high temperature (typically for $T > 450 \text{ K}$).^{44,45} Therefore, such compounds are generally not used as initiators in synthetic radical chemistry.

2.5 Persistent Radical Initiators

Persistent radicals have meanwhile found many applications in organic synthesis and polymer science. A detailed description of the persistent radical effect is given in other articles of this encyclopedia (see **Nitroxides in Synthetic Radical Chemistry**, **Nitroxide-Mediated Polymerization and its Applications**, and **Fundamentals of Controlled/Living Radical Polymerization**). Controlled polymerization mediated by persistent radicals represents a rapidly emerging field in polymer science. Nitroxides, which are probably the most widely used persistent radicals, play an important role in the well-known nitroxide-mediated polymerization (NMP, see **Nitroxide-Mediated Polymerization and its Applications**).^{8,9}

Nitroxides can be generated by thermolysis of alkoxyamines through an O–C bond cleavage process. The BDE is typically in the 20–35 kcal mol^{-1} range depending on both the alkyl and nitroxide fragments. Some typical compounds are depicted in Scheme 4. 2,2,6,6-Tetramethyl-piperidine-*N*-oxyl (TEMPO), 2,2,5-tri-methyl-4-phenyl-3-azahexane-3-nitroxide (TIPNO), and *N*-(2-methylpropyl)-*N*-(1-diethylphosphono-2,2-dimethylpropyl)-*N*-oxyl (SG1) are important members of this substance class. For 1-phenyl-1-(2',2',6',6'-tetramethyl-1'-piperidinyloxy)ethane, the rate constant of thermal C–O bond homolysis is $2.8 \times 10^{-6} \text{ s}^{-1}$ at 350 K

Scheme 4 Decomposition of alkoxyamines.

in cyclohexane. Rate constants for C–O bond homolysis in alkoxyamines are strongly affected by the structures of the alkyl and nitroxide fragments and lie typically in the range of 10^{-3} to 10^{-7} s^{-1} at 350 K.^{46,47}

2.6 The “Cage” Effect

The quantum yield of the thermal dissociation process in solution is usually reduced as compared to thermolysis in the gas phase. In contrast to the gas phase experiment, homolysis of an initiator in the liquid phase leads to the generation of two radicals that exist for a given time as a radical pair (RP) keeping the spin memory. The surrounding solvent molecules create a cage around the RP. In such an RP, where the two radicals have opposite spins, radicals can easily recombine before escaping from the solvent cage (i.e., this recombination occurs inside the solvent cage). The recombination rate constant between the two radicals is usually very high. The cage effect was first recognized in the 1930s by Frank and Rabinowitch.^{48,49} Importantly, this effect is not restricted to thermal processes and is also observed in the solution phase radical generation through photolysis. However, owing to spin considerations on the precursor excited states, evolution of RPs is more complicated in the photochemical process.

Cage effect strongly depends on solvent viscosity and temperature. For an efficient radical initiation, the recombination in the geminate RPs should be as low as possible. This in-cage/out-of-cage ratio is usually non-negligible. A typical value

of about 20% has been reported for the in-cage recombination of radicals during the thermolysis of AIBN, meaning that only about 60% of the radicals escape the cage and are ready for initiating a chain reaction.⁵⁰ This recombination and cage effect is also very important for spectroscopic investigations of radicals, that is, in the chemically induced dynamic nuclear polarization (CIDNP) or in the chemically induced dynamic electron polarization, CIDEP (see **Structures and Reactivity of Radicals Followed by Magnetic Resonance**).^{51–53}

3 ORGANOBORANE INITIATORS

Alkyl radicals can be very efficiently generated from trialkylboranes through interaction with molecular oxygen (organoborane derivatives are generally sensitive to O_2 and must be stored under argon) (Scheme 5). This oxidation reaction is quite efficient.^{54–57}

Trialkylboranes and more especially Et_3B have been intensively used as RIs in organic synthesis (see **Boron in Radical Chemistry**). Indeed, compared to other typical initiators that are activated by thermolysis (such as peroxides or azo compounds), Et_3B can act as an efficient

Scheme 5 Generation of ethyl radicals for the triethylborane/ O_2 system.

radical generator even at very low temperatures (at -78°C).² Low temperature initiation is very important for stereoselective radical chemistry (see **Stereoselective Radical Reactions**). Importantly, these reactions require only traces of oxygen. Processes are easily triggered by supplying oxygen through an air stream. It has been reported that Et_2Zn and 9-borabicyclo(3.3.1)nonane (9-BBN) are also able to initiate radical reactions upon treatment with air.^{58,59}

4 PHOTOCHEMICALLY ACTIVATED RADICAL INITIATORS

4.1 Homolytic Cleavage Process

Homolysis of single bonds can also be induced, at room temperature, by light (particularly by UV light). Radiation allows homolytic cleavage of a σ -bond to generate the corresponding radicals. Cleavage occurs from the excited states (singlet S_1 or triplet T_1) from which the dissociation process is more favorable than from the ground state S_0 . The promotion of an electron usually from the highest occupied molecular orbital (HOMO) (corresponding to a bonding or nonbonding orbital) to the lowest unoccupied molecular orbital (LUMO) (corresponding to an antibonding orbital) is responsible for weakening of bonds in the excited states.

Photoinduced homolysis offers decisive advantages over thermolysis: stronger bonds can be broken, that is, C–C bonds (see Table 4). Moreover, fewer side reactions are generally observed using photochemical activation allowing for cleaner radical generation. In photolysis, two important parameters govern radical formation:

1. The light absorption properties and more specifically the spectral sensitivity. Indeed, an excellent matching of the RI absorption spectrum with the emission spectrum of the irradiation device (light source: Hg lamp, Xe lamp, green fluorescence lamp, laser, LED, etc.) ensures the absorption of a large amount of photons. Different photochemical reactors have been designed to render photochemically induced radical reactions highly efficient.
2. The cleavage quantum yield (Φ_c), which represents the number of bonds broken per photon

absorbed. The cage effect is already included in this particular parameter. A quantum yield of 1.0 means that each absorbed photon leads to a dissociation reaction with the formation of two free radicals. However, Φ_c values less than 1.0 are usually observed because other pathways competing with the dissociation process such as, fluorescence, intersystem crossing, phosphorescence, internal conversion (as considered within the classical Perrin-Jablonski diagram of a single molecule), and excited state oxygen quenching, along with other side reactions are followed in the excited states.⁶⁰

Various compounds containing chemical bonds cleavable under light exposure have been reported in the literature. These initiators will now be briefly reviewed.

Photolysis of peroxides (or acylperoxides) via cleavage of the O–O bond is well established. This process leads to alkoxy (or acyloxy) radicals. However, these molecules mainly absorb at wavelengths $\lambda < 300\text{ nm}$. Since commonly used glassware absorbs all light above $\lambda < 310\text{ nm}$, often special glassware has to be used.

For azo compounds, the same issue must be considered, as a very weak absorption at wavelengths higher than 300 nm is noted, except with AIBN which exhibits a relatively intense absorption band around 340 nm . Starting with AIBN, isobutyronitrile radicals are readily generated by UV irradiation.⁶⁸

Some examples on photolysis of organohalide derivatives exhibiting relatively weak C–halogen bonds have been reported. As alkyl chlorides absorb at very short wavelength ($\lambda < 200\text{ nm}$), only iodides and bromides can be used because of their significant absorption at $200 < \lambda < 350\text{ nm}$. More particularly, alkyl iodides cleave efficiently.^{10–16,69,70}

The photolysis of heteroatom–halogen or heteroatom–heteroatom bonds, for example, in *N*-chloroamines ($\text{R}_2\text{N–Cl}$) and hypochlorites (RO–Cl), also occurs with formation of the corresponding alkoxy and aminyl radicals^{11,71}:

Thiyl radicals can be generated via photolysis of the S–S bond in disulfides, albeit this method suffers from the low light absorption of the precursors at

Table 4 Cleavage quantum yields ϕ_c of various photoinitiators.

Bond dissociation energies (BDE) calculated at B3LYP/6-31G(d) level.⁶¹^aMeasured by laser induced photoacoustic calorimetry.⁶¹

$\lambda > 320$ nm (reaction 13). This is a straightforward way for the formation of thiyl radicals, as in symmetrical disulfides only one kind of thiyl radical is generated. Therefore, this approach has been successfully used in many physical chemistry studies on thiyl radicals.^{72–75}

Bond homolysis can also be induced by energy transfer and/or electron transfer using a photosensitizer, PS, with adjusted light absorption properties⁷⁶:

The formation of dithiocarbamyl radicals from the photolysis of benzyldithiocarbamates has also been reported as an efficient process:

Dithiocarbamyl radicals have been used to control the photopolymerization reaction of different monomers (acrylate, methacrylate, styrene, etc.). In that case, the RI is called a *photoiniferter* (see **Reversible Addition Fragmentation Chain Transfer (RAFT) Polymerization: Mechanism, Process and Applications**).⁷⁷

Upon photolysis of thiols, thiyl radicals are also generated; however, the light absorption for these compounds is still worse as compared to disulfides (Ref. 78 and references therein):

More interestingly, nitrites can generate alkoxyl radicals via photochemical O–N bond cleavage (reaction 18). These precursors are interesting as they exhibit quite good light absorption properties owing to the presence of a $n\text{--}\pi^*$ transition at around 360 nm.⁷⁹

The cleavage of different Si–B bonds with the formation of silyl and boryl radicals under light irradiation were also reported but these precursors suffer from a low light absorption at $\lambda > 300\text{ nm}$ ⁸⁰:

Silyls radicals can be generated by the cleavage of disilane precursors ($\text{R}_3\text{Si--SiR}_3$). This Si–Si dissociation process under light irradiation is well known in polysilanes.³⁴ Some organic precursors that show good light absorption in the more convenient 300– to 400-nm range were more recently proposed.^{81,82}

In organic synthesis, photolysis of alkyliditins has been often applied as an important process for generation of tin radicals, which are highly important in the field of synthetic radical chemistry (see **Tin Hydrides and Functional Group Transformations**). Other photoinduced metal–metal bond cleavage processes for various compounds containing an Se, Te, Mn, Re, Fe, Mo, or Ru atom can be useful in initiating a chain reaction (reactions 20–27).^{10–16,83–89} This is mainly related to the $\sigma\text{--}\sigma^*$ transition, which ensures, after light absorption, formation of a dissociative excited state. Good to excellent light absorption properties are found, that is, the Mn, Mo, and Te derivatives exhibit high absorption coefficients in the visible spectral range; for example, for $\text{Cp}_2\text{Mo}_2(\text{CO})_6$, a significant absorption is found, $750\text{ M}^{-1}\text{ cm}^{-1}$ at 532 nm.

The cleavage of a Co–C bond occurs in Co(III) complexes, which are used, for example, for the radical generation in vitamin B₁₂ (see **Radical Enzymes**)^{90,91}:

The photolysis of a Hg–C bond is also a very efficient process for clean C-radical generation. Importantly, the BDE for Hg–C bonds is very low:

For clean and efficient generation of free radicals in organic synthesis, different classes of organic initiators with absorption spectra matching the emission spectra of classical and common UV–visible lamps have been designed. Particularly, derivatives of *N*-hydroxypyridine-2-thione esters (or *N*-hydroxyquinazoline-4-thiones)^{92–94} and *N*-hydroxypyridine-2-thione carbamates⁹⁵ were proposed as efficient sources of carbon-centered (Scheme 6) and aminyl radicals, respectively. These structures can also be activated by thermolysis.⁴²

N-Hydroxypyridine-2-thione esters are highly interesting reagents since they allow initiation of chain reactions. Propagation is achieved through an addition/ β fragmentation sequence (Scheme 7; see **Xanthates and Related Derivatives as Radical Precursors**). The addition of an $\text{R}'^\bullet$ radical to the C=S bond is usually exothermic and leads to a carbon-centered radical. A favorable β -fragmentation (which corresponds to a monomolecular reaction) occurs with concomitant formation of an aromatic ring; after decarboxylation, a new radical is eventually released ($\text{R}'^\bullet$).

Scheme 6 Radical formation in *N*-hydroxypyridine-2-thione esters.

Scheme 7 Addition β -fragmentation in *N*-hydroxypyridine-2-thione esters.

With these precursors that allow generation of radicals in a clean manner, different competitive methods were proposed in kinetic investigations for assessing reaction rate constants of alkyl radicals.⁹⁶ Different radical clocks have been developed using these radical precursors (see **Radical Kinetics and Clocks**).⁹⁷

Many typical organic initiators have been optimized for good light absorption in the UV range and more particularly in the 300–400 nm domain. These compounds are used for organic synthesis, physical chemistry studies, and also as photoinitiators (PI) for free radical photopolymerization (see e.g., Refs 64, 98). UV and visible light-initiated polymerizations have become one of the most important methods used in radiation curing area.^{99–102} In polymer chemistry, compared to thermal initiation processes, several practical advantages of industrial applications of photoinitiation can be listed (see **Radical Polymerization in Industry**): the photopolymerization process is subjected to a strict spatial control; it is easily switched on or off at demand; interestingly, solvent-free systems are employed, meeting the requirements for green chemistry.

Typical PI structures undergoing efficient photolysis are gathered in Table 4. The PI, usually bearing a carbonyl group, is promoted to its first excited singlet state S_1 by light absorption and then, through intersystem crossing, to its excited

triplet state T_1 . The intersystem crossing quantum yields (Φ_{isc}) are usually high (often close to 1 for ketones).¹⁰³ The α -carbonyl bond cleavage process (often called Norrish I type cleavage) occurs from the T_1 state and corresponds to the frequently encountered primary step (Scheme 8). The spectral absorption range and Φ_c for typical PIs are given if available in the literature; reported Φ_c values often have a large uncertainty and therefore only the more representative values are included. The bond dissociation energies of the cleavable bond (C–C and C–P) are also presented in the table.

Germyl radicals can efficiently be generated from acylgermanes under light irradiation. These compounds show excellent light absorption at $\lambda > 350$ nm^{104–107}:

Interestingly, bis(germyl)ketones were reported to be useful Ge-radical precursors that adsorb visible light (with $\lambda_{max} \sim 515$ nm)¹⁰⁸:

These structures were recently proposed as PIs in free radical polymerization.¹⁰⁹

For some ketones, β -cleavage occurs after irradiation. This can be observed for β -halogenated ketones and also for β -sulfonyl ketones (e.g., bifunctional ketone–sulfonyl ketone derivatives exhibit an interesting absorption around 410 nm) (Scheme 9).^{110–112}

Scheme 8 α -Cleavage process in aromatic ketones.

Scheme 9 β -Cleavage process for halogenated ketone derivatives and for sulfonyl ketones.

4.2 Hydrogen Abstraction Reaction

Another route for generation of radicals uses bimolecular hydrogen abstraction reactions. This generally occurs in a molecule (in most of the cases bearing a carbonyl group) in its triplet state T_1 . Using a large range of precursors, the absorption properties can be tuned from the UV (benzophenone) to the near visible (thioxanthone) or the visible wavelengths (camphorquinones, coumarins, dyes, etc.). Hydrogen abstraction usually occurs in the triplet state for ketones or aldehydes (i.e., acetone, acetophenone, benzophenone, thioxanthone, camphorquinone, coumarin derivatives, benzaldehyde, etc.).¹⁰³

This reaction corresponds either to a hydrogen transfer process or an electron transfer followed by a proton transfer (e^-/H^+ mechanism) (Scheme 10).

The competition between these two mechanisms is related to the redox properties of the reactants. The free-energy changes (ΔG_{Et}) for the electron transfer from a donor to an acceptor can be calculated from the classical Rehm–Weller equation (33), where E_{ox} is the oxidation potential of the donor, E_{red} is the reduction potential of the acceptor, E_T is the triplet state energy (or the excited state energy), and C is a coulombic term for the initially formed ion pair (C is often neglected in polar solvents).¹¹³ For systems having a negative ΔG_{Et} , the electron/proton transfer sequence is very favorable.

Scheme 10 Hydrogen transfer and electron–proton transfer sequence for the benzophenone triplet state.

Table 5 Typical hydrogen donors and rate constants for H-transfer to the benzophenone triplet state (^3BP) or the *t*-butoxyl radical ($t\text{BuO}^\bullet$).

Hydrogen donors	$k(^3\text{BP})$ in $10^7 \text{ M}^{-1} \text{ s}^{-1}$	Mechanism	$k(t\text{BuO}^\bullet)$ in $10^7 \text{ M}^{-1} \text{ s}^{-1}$	Generated radicals

^jReference 123.

Typical hydrogen donors include amines, thiols, alcohols, ethers, silanes, boranes, aliphatic or aromatic hydrocarbons, and so on.^{103,114} For the first two classes (amines and thiols), the process is described by an electron–proton transfer sequence whereas a pure hydrogen transfer is usually expected for the other structures. Typical rate constants characterizing the reactivity of the benzophenone triplet state (^3BP) with different representative hydrogen donors are gathered in Table 5. For triethylamine and mercaptobenzoxazole (which are good representatives of amines and thiols), H-abstraction rate constants lie close to the diffusion limit and are higher than the corresponding rate constants for H-transfers to $t\text{BuO}^\bullet$. This is in agreement with the fulfilled condition $\Delta G_{\text{Et}} < 0$, supporting the e^-/H^+ mechanism. In the ^3BP reaction with alcohols, silanes, germanes, stannanes, or ligated boranes, $\Delta G_{\text{Et}} > 0$ and the e^-/H^+ mechanism is not favorable. The rate constants for H-transfer of these hydrogen donors to ^3BP or $t\text{BuO}^\bullet$ are quite similar. For these processes, ^3BP behaves like an alkoxyl radical.

Quantum yields for ketyl radical formation (obviously equal to the quantum yields for the production of the radical derived from the hydrogen donor) are usually quite high (Table 5). The interaction of ketone triplet states with hydrogen donors is an efficient process in the radical photoinitiation step. Many radicals can be generated through this route:

alkyl, aminoalkyl, aminyl, silyl, germyl, stannyl, boryl radicals, and so on.

In addition to ketones discussed above, other compounds have gained great attention to be used in hydrogen abstraction processes. For example, decatungstate acts as an efficient photocatalyst in organic chemistry (reactions 34–37). The excited state of this compound abstracts a hydrogen atom from a large range of donors (R-H)^{124–128}:

This process has been successfully used for radical C–C bond formation via addition of an activated alkane RH to an unsaturated olefin (H-transfer addition reaction):

Decatungstate exhibits high reactivity under visible light; even sunlight can be applied to run these reactions! Interestingly, the use of this photocatalysts in organic synthesis does not require any specific photochemical equipment.

Table 6 Radical initiation through an oxidation process.

Precursor	Oxidizing agent	Expected reaction
Carboxylates	Electrochemical method (Kolbe reaction)	$\text{RCO}_2^- \longrightarrow \text{RCO}_2^\bullet + \text{e}^-$
Phenoxydes	Electrochemical method	$\text{ArO}^- \longrightarrow \text{ArO}^\bullet + \text{e}^-$
Carboxylic acids	Strongly oxidizing metal ions (typically silver II)	$\text{M}^n + \text{RCO}_2\text{H} \longrightarrow \text{M}^{n-1} + \text{RCO}_2^\bullet + \text{H}^+$
Alcohols	Strongly oxidizing metal ions	$\text{M}^n + \text{ROH} \longrightarrow \text{M}^{n-1} + \text{RO}^\bullet + \text{H}^+$
Alkylbenzene derivatives	Ce(IV)	$\text{Ce}^{4+} + \text{PhCH}_3 \longrightarrow \text{Ce}^{3+} + \text{PhCH}_2^\bullet + \text{H}^+$
Carbonyl derivatives (more effective for carbonyl being able to enolize)	Mn(III)(OAc) ₃	$\text{R}-\overset{\text{O}}{\parallel}{\text{C}}-\text{CH}_2-\overset{\text{O}}{\parallel}{\text{C}}-\text{R}' + \text{Mn}(\text{OAc})_3 \longrightarrow \text{R}-\overset{\text{O}}{\parallel}{\text{C}}-\dot{\text{C}}\text{H}-\overset{\text{O}}{\parallel}{\text{C}}-\text{R}' + \text{Mn}(\text{OAc})_2 + \text{AcOH}$

The radicals generated appear in bold face.

5 REDOX REACTIONS

Radicals can also be generated via redox processes (see **Electrochemically Initiated Radical Reactions, Organic Electron Donors**) through either reduction or oxidation of an appropriate precursor (RX):

Contrary to the cleavage processes observed in thermolysis and photolysis, the redox process possesses the intrinsic advantage to generate only one radical (instead of a pair of radicals). Within this article, oxidation and reduction reactions will be discussed independently in the following two sections.

5.1 Oxidation

The precursor (R-X) reacts with strongly oxidizing agents such as metal salts of cerium(IV), manganese(III), and silver(II).^{10–16,129,130} These compounds can be used for the oxidation of a large variety of compounds with concomitant formation of free radicals. Some typical examples are gathered in Table 6.

5.2 Reduction

The precursor (R-X) must accept an electron from a reagent that can donate an electron (Table 7). A look at the respective redox potentials of both reactants can indicate the feasibility of such a redox process. Particularly, the addition of an electron to halides is well known as an efficient process for radical generation. The electronegativity of the halogen atom

Table 7 Radical initiation through a reduction process.

Precursor	Reducing agent	Expected reaction
Halides	Sm(II), Co(I), Fe(II), Ru(II)	$\text{M}^n + \text{RX} \longrightarrow \text{M}^{n+1} + \text{R}^\bullet + \text{X}^-$
Peroxides	Co(II), Fe(II), Cu(I), Cr(II), V(II), Ti(III)	$\text{M}^n + \text{RO-OR}' \longrightarrow \text{M}^{n+1} + \text{RO}^\bullet + \text{R}'\text{O}^\bullet$
Arene diazonium salts	Co(I) or strong organic reductants	$\text{M}^n + \text{ArN}_2^+ \longrightarrow \text{M}^{n+1} + \text{Ar}^\bullet + \text{N}_2$
Carbonyl	SmI ₂	$\text{SmI}_2 + \text{R}-\overset{\text{O}}{\parallel}{\text{C}}-\text{R}' \longrightarrow \text{R}-\overset{\text{O}^-\text{SmI}_2}{\underset{\cdot}{\text{C}}}-\text{R}'$
Persulfate	Silver I	$\text{Ag}^+ + \text{S}_2\text{O}_8^{2-} \longrightarrow \text{Ag}^{2+} + \text{SO}_4^{\bullet-} + \text{SO}_4^{2-}$

The radicals generated appear in bold face.

ensures that X^- will be generated from the corresponding radical anion $RX^{\bullet-}$. Samarium(II) (see **Organic Synthesis Using Samarium Diiodide**), iron, copper, and ruthenium complexes were used for the reductive generation of $R^\bullet$.^{129,130} Some organic single electron transfer reductants were also developed (see **Organic Electron Donors**).^{131–140} The reduction of peroxides via transfer of an electron into the antibonding orbital (σ^*) weakens the RO–OR bond inducing the cleavage of the σ -bond, thereby liberating an anion and the corresponding O-centered radical. This process occurs in the well-known iron(II)/hydrogen peroxide system. This corresponds to the Fenton reaction, which allows generation of hydroxyl radicals. Some cobalt salts in combination with peroxides are also known to initiate a free radical polymerization process at room temperature. Other reductants such as Cr^{2+} , V^{2+} , Ti^{3+} , Co^{2+} , and Cu^+ can also be employed in place of ferrous ions.

5.3 Electrochemical Methods

The direct oxidation (or reduction) of an anion (or a cation) by electrochemical methods also leads to radical formation^{141–143}:

Typical examples of electrochemical oxidation/reduction-induced radical generation will be discussed in **Synthetic Electrochemistry**, Volume 2.

5.4 Photoactivated Redox Processes

Redox reactions can also be promoted by light as the excited states (singlet or triplet state) are often better oxidation or reduction agents than the corresponding ground states. This is related to the promotion of an electron from the HOMO to the LUMO. Indeed, in a schematic approach (Scheme 11), the ionization potential is decreased (the electron will be abstracted from the initial LUMO for the excited state instead of the HOMO for the starting molecule). In a similar way, the electron acceptor properties of the excited state are also enhanced, that is, in the case of an

Scheme 11 Orbitals involved in the oxidation or reduction processes for the ground and excited states.

excited acceptor molecule, the donor electron is transferred to the initial HOMO; for a ground state molecule, this occurs in the LUMO (Scheme 11).

The redox process is governed by the Rehm–Weller equation (33), which gives indication about the feasibility of the process. The electron transfer process can be followed by a proton transfer reaction from appropriate hydrogen donors resulting in a net hydrogen transfer process (see Section 4.2). The generation of aminoalkyl radicals by such a light-activated process in ketone/amine systems has been used in some synthetic organic and polymer applications. A detailed description is given in **Synthetic Radical Photochemistry**. (Refs 144, 145 and references therein).

Very recently, photochemically induced electron transfer from transition metals has also gained great attention, particularly for synthetic applications.^{146–152} This process is called *photoredox organocatalysis*. The selected photocatalysts are mainly based on Ru or Ir ($Ru(bpy)_3^{2+}$, $Ir(ppy)_2(dtb-bpy)^+$, etc.) and are characterized by an intense visible light absorption. These catalysts are more efficient than dicyanoanthracene. Very interestingly, with these compounds, very convenient visible light sources—including fluorescent bulbs and ambient sunlight—can be used.

As far as the mechanism is concerned, it is assumed that the excited state of the organocatalyst reacts with a sacrificial quencher through an electron transfer reaction (amine, methyl viologen, enamine, etc.) and generates a strong reductant or oxidant metal complex. For example, $Ru(bpy)_3^{3+}$ (or $Ru(bpy)_3^{3+}$) is generated by reduction (or oxidation) of the $^*Ru(bpy)_3^{2+}$ excited state by an amine (or methyl viologen (MV^{2+})) (Scheme 12). For $Ir(ppy)_2(dtb-bpy)^+$, a strong $Ir(ppy)_2(dtb-bpy)$

Scheme 12 Formation of Ru(bpy)₃⁺ and Ru(bpy)₃³⁺ in a light-activated process.

reductant is formed by reaction of the corresponding excited state with a sacrificial enamine.^{146–152}

These strong reductants or oxidants can be used to promote radical reactions.^{146–152} For example, CF₃[•] radicals can be generated by a single electron transfer from Ir(ppy)₂(dtb-bpy) to CF₃I.¹⁵² Using Ru-based systems, aryl enones can be reduced to the corresponding radical anions. For electron-rich olefins, the oxidation pathway can be operative to generate the corresponding radical cations. These intermediates can be used in [2+2] cycloadditions.^{146–151}

6 OTHER MODES

Radiolysis (for example, X-ray or γ-radiation) causes the ejection of an electron from the initiating species, leading to the formation of a radical cation that further decomposes to a radical and a cation; see also **Radiation-Induced Radical Reactions**.^{153–156} The associated mechanisms are often quite complex and this mode of activation involving high energy is not really considered as selective. Using water, highly reactive hydroxyl radicals (45%) together with hydrated electrons (45%) and hydrogen atoms (10%) are generated as primary species (reactions 42, 43):

Radiolysis is an important method for radical generation in food applications. Indeed, the irradiation of food generates highly reactive radicals (like OH[•]) that kill the contaminating organisms leading to a food preservation process.

Pulsed radiolysis is a powerful technique to initiate fast reactions. The sample is exposed to a beam of highly accelerated electrons. The transient intermediates can be followed by UV–visible spectroscopy. This method is highly useful to study fast reactions and chemical intermediates (typically in a microsecond–millisecond timescale).^{153–160}

γ-Radiation from ⁶⁰Co has been successfully applied to initiate polymerizations and grafting processes.^{153–156,160,161}

The electron beam induced polymerization (EB curing) belongs to the radiation curing field with important applications (particularly for coatings) in industry.^{162,163}

In sonication with high-intensity ultrasound waves, radical generation results from the effects of cavitation (formation and collapse of cavities in the liquid). High local temperatures and pressures are reached, leading to bond breaking and radical formation.^{164,165}

7 CONCLUSIONS

As shown in this article, the generation of radicals can occur through several different routes. Most of these approaches have been applied as will be presented in many articles of this encyclopedia, in Chemical Synthesis (Volume 2), in Chemical Biology (Volume 3) and also in Polymers and Materials (Volume 4). However, there is still a need for the development of new RIs that allow clean radical generation under mild conditions fulfilling various criteria: low temperature, soft irradiation (sunlight or green fluorescence bulbs), and being highly selective.

1 INTRODUCTION

Although radicals are very reactive species, owing to their electron deficiency, they can be useful in selective transformations. They are neutral species, and therefore their reactivity is not strongly influenced by solvents. Knowledge of the rate constants for the competing radical reactions permits predictive control of the reactivity. Here, we briefly address free radical processes induced by light, which is one of the most important ways to generate these intermediates (see **Synthetic Radical Photochemistry**). Homolytic cleavage, electron transfer coupled to proton transfer, and electron transfer followed by anion dissociation can occur after light absorption or in the presence of a photosensitizer that absorbs light, finally resulting in the removal of groups or generation of new bonds such as carbon–carbon, carbon–oxygen, carbon–sulphur, carbon–selenium, and carbon–halogen, among others (Scheme 1). In this article, we consider the various photochemical strategies to generate carbon radicals and show examples that underline the interest in these species in synthetic chemistry.

2 ONE-STEP PROCESSES

2.1 Homolytic Cleavage

2.1.1 X–Y Bond Cleavage: C–Y (Y = halogen, C, S, N) and O–Y (Y = I, N, Cl, S)

C-Halogen α -Cleavage of Haloalkanes

The lowest energy transition of haloalkanes involves promotion of one of the electrons of the

halogen to the σ^* orbital of the carbon–halogen (C–X) bond; the wavelength required for excitation depends on the halogen atom and on the substituents attached to the carbon atom.¹ Light absorption causes cleavage of the C–X bond; the relative ease of this process is opposite to the C–X bond strength, that is, C–I > C–Br > C–Cl > C–F. In addition, it also depends on the substituents of the carbon atom. Thus, although direct photolysis of the C–F bond is rare, all benzylic halides undergo light-induced cleavage.

The C–X bond cleavage leads to radical pairs, which can escape from the cage in nonpolar solvents or undergo electron transfer to generate a carbocation and a halide anion (Scheme 2). Chloroalkanes are less prone to generate cationic species than bromoalkanes and these are less prone than iodoalkanes.²

Laser flash photolysis of substituted benzylic halides has allowed the detection of benzylic radicals and cations.³ The homolytic and heterolytic bond fragmentations arise not only from the singlet excited states but also from the triplet excited states, as shown by selective excitation of chlorides in their triplet states by triplet energy transfer from, for example, acetophenone. Carbon–halogen homolysis in (halomethyl)naphthalenes has been postulated to occur also from an exciplex of the halide with a singlet or triplet sensitizer.⁴ This exciplex would cleave heterolytically in a polar solvent but homolytically in a nonpolar solvent such as cyclohexane.

Steady-state irradiation in cyclohexane of a benzylic chloride, such as 1-chloro-1,5-diphenylpentane,

A wide range of benzylic systems, such as benzylic acetates, or benzylic sulphonium, ammonium, and phosphonium salts, have also been investigated.⁷ They follow the reactivity pattern of the more systematically studied benzyl halides.

In addition, photolysis of α -haloesters, α -halonitriles, and α -haloamides (halogen = Br, I) leads to electron-deficient radicals. These radicals have been applied to the radical aromatic substitution of pyrroles and indoles (Scheme 4b).⁹ Carbon-carbon bond formation is followed by addition of the halogen (X) atom and then loss of HX to regenerate the aromaticity. Addition of a reductant, such as $\text{Na}_2\text{S}_2\text{O}_3$, in the presence of a phase-transfer catalyst ($\text{Bu}_4\text{N}^+ \text{Br}^-$) has been used to consume the molecular iodine (bromine) generated as a by-product of the reaction; this methodology avoids the use of distannanes as reductants. Propylene oxide is added to trap the HI (or HBr) produced in the reaction. In the case of iodocycloalkanones bearing an allenyl side chain, the halogen atom remains attached to the final compound.¹⁰

Moreover, 1,*n*-dihaloalkanes ($n \geq 1$) can be precursors of *n*-haloalkyl radicals. Chloroalkyl radicals have the characteristic features of the corresponding

Scheme 3

Scheme 4

carbon radicals, such as high reactivity toward oxygen (diffusion-controlled quenching) and absorption spectra (λ_{max} at 320 nm for *n*-chloroalkyl phenyl radicals). By contrast, the behavior of *n*-bromo- and *n*-iodoalkyl radicals supports the predominance of a bridged structure, that is, a hypervalent halo

radical, mainly in the case of the iodine species (Scheme 5).^{6–14}

n-Chloro-1,*n*-diphenylalkyl radicals and *n*-iodo-1,*n*-diphenylalkyl radicals have been proved to photolyze to 1,*n*-diphenylalkanedyl biradicals when irradiated at a wavelength matching their optical

Scheme 5

Scheme 6 Two-photon homolysis of 1,5-diiodo-1,5-diphenylpentane.

absorption. The laser drop technique has made it possible to perform product studies under high intensity irradiation conditions while minimizing the amounts of secondary products. Such studies have demonstrated that 1,5-diphenyl-1, n -alkanedyl biradicals mainly cyclize to 1,2-diphenylcyclopentane when photolyzing the iodine-stabilized radical⁶ (Scheme 6), whereas in the case of the chloro-analogs, they mainly undergo disproportionation. This agrees with the cyclic character of iodine radicals.

C-Halogen α -Cleavage of Haloalkenes and Haloarenes

Homolysis of the C–X bond in haloalkenes affords vinyl radicals, whose main reaction is hydrogen or

halogen atom abstraction.¹⁵ Homolytic cleavage of aryl carbon–halogen bonds produces aryl radicals, which can participate in a radical aromatic substitution or abstract hydrogen from a donor.¹⁶ Homolysis requires that the energy of the reactive species be greater than the C–X bond dissociation energy. In simple benzene derivatives, the energy of the excited states is similar to that of many halogen–aryl bonds. However, the process is less likely in polycondensed aromatics because of the lower energy of their excited states.

O–I α -Cleavage of Iodanes

Alkoxy radicals are involved in the photooxidation of hydrocarbons and biological systems. These radicals can be generated photochemically from alcohols by visible light irradiation of dichloromethane solutions containing a hypervalent iodine reagent, such as the (diacetoxy)-iodobenzene (DIB)/I₂ system¹⁷ or bis(pyridine)iodonium tetrafluoroborate (IPy₂BF₄).¹⁸ The O–I cleavage of an iodane intermediate under light excitation leads to an alkoxy radical (Scheme 7a). The C–C β -scission of the alkoxy radicals provides a carbonyl compound and an alkyl radical. This is a reversible reaction, which generally leads to homolysis of the C–C bond belonging to the most significantly strained substructure and produces the most stabilized carbon radical. Therefore, the regioselectivity of this reaction is generally predictable, thus allowing the synthesis of aldehydes and ketones from alcohols under neutral conditions.

An example of the application of C–C β -scission of alkoxy radicals in organic synthesis is the photolysis of steroidal lactols under inert atmosphere, which, after formation of the alkoxy radical, undergo β -fragmentation and provide C-centered radicals; subsequent loss of a hydrogen atom affords medium-sized lactones in good yield (Scheme 7b). Similar fragmentations have been applied to the preparation of a variety of medium-sized ketones and aldehydic biquinanes. In addition, fragmentation of anomeric alkoxy radicals from carbohydrates provides a convenient entry into chiral building blocks (see **Radical Arylations**). Furthermore, ketones have been prepared in high yield by means of cascade radical fragmentation–transannular cyclization sequences (Scheme 7c).

Scheme 7

N-O α -Cleavage of N-Alkoxy Compounds

Nitrite esters can be prepared by reaction of alcohols with nitrosyl chloride.¹⁹ The Barton reaction involves photolysis of the N–O bond of a nitrite ester to generate an alkoxy radical, which abstracts a hydrogen atom from an appropriate C–H bond, leading to an alkyl radical (Scheme 8a). Recombination in the solvent cage produces a nitroso alcohol.²⁰ In the presence of oxygen, this can eventually lead to a nitrate ester. The Barton reaction has

allowed the functionalization of remote and nonactivated positions in steroids (Scheme 8b), as well as the synthesis of cyclic alkenes from γ,δ -unsaturated alcohols.

In addition, a carboxylic acid can be converted into a thiohydroxamate ester (Scheme 9).²¹ Homolytic cleavage of the N–O bond leads to a 2-pyridylthiyl radical and an acyloxy radical. After decarboxylation, the alkyl radical reacts with a broad range of compounds, such as alkenes,

Scheme 8

Scheme 9

disulfides, seleno compounds, and sulfur dioxide, as well as with phosphorus or other elements (Scheme 9). This reaction has been shown to be versatile for the synthesis of biologically active compounds such as carbohydrates, amino acids, vitamins, and terpenoids.

C–O α -Cleavage of Aromatic Ethers and Esters

The photorearrangement of aromatic ethers (photo-Claisen)²² and esters (photo-Fries)²³ is a classical photochemical process of aromatic molecules, which are mechanistically related (Scheme 10). It consists in the formation of a singlet radical pair (a carbon-centered and an oxygen-centered radical) within a solvent cage after homolysis of an aryloxy–alkyl (photo-Claisen) or an aryloxy–acyl bond (photo-Fries),²⁴ followed by in-cage recombination to *ortho*- and *para*-coupled products. Experimental evidence for this process comprises, among others, (i) detection of phenoxy radicals,^{25,26} (ii) spin trapping of radicals,²⁷ and (iii) measurements of magnetic isotope effects and external magnetic field effects on formation of the resulting products.²⁸

Quantum yields of the photoproducts do not reflect the excited state reactivity. This is because of a predominant C–O versus C–C coupling, which has been demonstrated in an intermolecular approach, where considerable recombination to the

starting material is observed. The quantum yield of the rearranged product is higher in hydroxylic solvents than in cyclohexane; this effect has been explained as being due to stabilization of an intermediate cyclohexadienone (Scheme 10). In fact, laser flash photolysis of benzyl phenyl

Scheme 10

ethers and phenyl acetate in methylcyclohexane has shown the appearance of a transient signal ($\lambda_{\max}$ at circa 305 nm), ascribed to the corresponding cyclohexa-2,4-dienones. Two-laser two-color laser flash photolysis has made it possible to detect the cyclohexa-2,4-dienone and its subsequent photolysis to a dienic ketene (Scheme 10).²⁹ The first laser (synthesis laser) generates the dienone with 266-nm pulses, whereas the second laser (photolysis laser) with 308-nm pulses matches the absorption of the cyclohexa-2,4-dienone.

These reactions have been chosen as models to study the influence of different media as modifiers of reactivity and selectivity.^{30–32} Studies have been performed in several constrained environments, such as polymers, cyclodextrins, and zeolites. Thus, the influence of medium polarity and polymer relaxation on the motion of the singlet radicals has been studied for the photo-Fries rearrangement of 1-naphthyl (*R*)-2-phenylpropanoate in poly(vinyl acetate) films in their glassy (5 °C) and melted (50 °C) states, and has been compared with the results in ethyl acetate, polyethylene films, and *n*-hexane.³³ These observations indicate that high stereo- and regioselectivities can be obtained if parameters such as the relationship between the rates of in-cage motion and cage-escape or between the rates of radical tumbling and translation are controlled.

Recently, the photo-Claisen reaction has been applied to the formation of micelles from a poly(4-allyloxystyrene)-block-polystyrene diblock

Scheme 11

copolymer in cyclohexane. The conversion of the 4-allyloxystyrene units reaches 90% after irradiation for 24 hours, and the isolated copolymer with a 35-nm hydrodynamic diameter aggregates into micelles with a 98-nm diameter (Scheme 11).³⁴

There are many variations of these reactions, which have been extended to other systems, such as anilides, phenoxyacetic acids, aryloxyacetones, sulfonanilides, carbonates, carbamates, sulfonates, benzyl amines, and benzyl alkyl ketones.

C–C α -Cleavage of Ketones

Excitation of alkyl and alkyl aryl ketones induces homolytic bond cleavage at the α -position of the carbonyl group, leading to alkyl acyl radical pairs (Scheme 12). Ketones exhibit reactivity in the excited state analogous to that presented by the alkoxy radicals in the ground state. Thus, the weakest α -bond is cleaved, leading to the most stable radical.^{35–38} In general, the reactivity increases with the stability of the generated radical and with strain release.

Scheme 12

Scheme 13

This reaction, known as the *Norrish type I reaction*, is faster for $n\pi^*$ than for $\pi\pi^*$ excited states, owing to the weakening of α -bond in the former by overlap with the half vacant n -orbital on oxygen. In addition, the α -cleavage reactivity of $n\pi^*$ triplets is circa 100 times higher than that of singlet excited states. As a consequence, the reaction is faster for aliphatic than for aromatic ketones, owing to the more stabilized triplet of the latter.

The generated radicals can undergo (i) mutual recombination, which explains that reaction quantum yields are less than unity; (ii) homocoupling; and (iii) disproportionation to an aldehyde and an alkene or a ketene plus an alkane (Scheme 12). In addition, the acyl radical can decarbonylate if a very stable radical is formed, as in the case of dibenzylketones.

In the case of cyclic ketones, new products arise owing to the possibility of secondary intramolecular reactions (Scheme 13). Thus, cyclobutanones can undergo ring expansion (exp.) to produce oxacarbenes, which react with nucleophiles such as alcohols. The product distribution will depend on the relative values of the rate constants of the different competing processes. Decarbonylation can predominate in the presence of radical-stabilizing groups at the α - and α' -positions, if no hydrogen atoms are accessible for disproportionation (disprop.), or when a significant ring strain is released by the loss of CO. Crystalline ketones with radical-stabilizing groups in the two α -positions can efficiently photodecarbonylate and lead to biradicals, which can eventually couple in an almost quantitative yield.³⁹

An example of the application of C–C α -scission of ketones is the synthesis of a precursor of the

Scheme 14

Scheme 15 Photogeneration and photolysis of acyl-alkyl radicals.

sesquiterpene (+)-juvabione by irradiation of an enantiopure bicyclo[3.3.1]nonanone⁴⁰ (Scheme 14). Photolysis of the ketone leads to the acyl-alkyl biradical, which disproportionates mainly to the aldehyde (66% yield).

Acyl-alkyl biradicals exhibit transient UV-absorption spectra, which are practically coincident with those of the corresponding alkyl radicals, since acyl radicals do not absorb at wavelengths longer than 300 nm. Thus, the spectrum of the acyl-alkyl biradical of 2-phenylcycloalkanones compares well with that of the corresponding benzyl radical. These intermediates undergo disproportionation under thermal conditions, while they decarbonylate to biradicals upon further irradiation, eventually leading to products arising from the dialkyl biradicals (Scheme 15).⁴¹ This process has been explained as occurring via light absorption by the benzyl radical, followed by an intramolecular energy transfer to the acyl radical.

C–S α -Cleavage of Thioethers

In general, thioethers undergo homolytic cleavage of the C–S bond from the singlet excited state. The resulting thiyl radicals mainly couple, whereas alkyl radicals stabilize via hydrogen abstraction, loss of a hydrogen atom, or coupling. In the presence

of nucleophilic or electrophilic alkenes, selective trapping of either of the two types of radicals occurs, taking into account the electrophilic or nucleophilic character of the radical partners.⁴²

C–N α -Cleavage of Azo Compounds

Azoalkanes exhibit $n\pi^*$ bands in the 300–400 nm region. This absorption is weak, but it is suitable for the photoextrusion of molecular nitrogen.⁴³ Theoretical and experimental evidence supports the stepwise elimination of nitrogen, via singlet or triplet diazenyl biradicals.

2.1.2 H-Abstraction

H-Abstraction by Ketones

As mentioned earlier, ketones exhibit reactivity in the excited state, which is analogous to that presented by alkoxy radicals in the ground state. The latter can abstract a hydrogen atom from a nearby C–H bond leading to an alkyl radical. Similarly, carbonyl $n\pi^*$ singlets and triplets can abstract a hydrogen atom from good hydrogen donors such as alkanes, alcohols, and ethers, leading to the formation of ketyl/alkyl radical pairs or, in intramolecular processes, ketyl-alkyl biradicals (Scheme 16).^{44,45} The efficacy of the process depends on the C–H bond strength and, in the intramolecular case, on conformational effects. Thus, the reaction generally proceeds through a 6-membered cyclic transition state with a chair conformation, being the Csp^3 –H at the γ -position—the one undergoing homolytic cleavage if it is close to the carbonyl group (Scheme 16). However, H-abstraction can also occur from other positions such as δ , β (if the γ and δ C–H are encumbered), and ε (less frequent).

For the same hydrogen donor, the rate of hydrogen abstraction increases with increasing triplet energy of the ketone; for example, $k_H = 6 \times 10^5$ or $3 \times 10^3 \text{ M}^{-1} \text{ s}^{-1}$ for hydrogen abstraction from isopropanol by benzophenone and biacetil, respectively. This process competes advantageously with α -cleavage of the carbonyl compounds. In addition, aromatic ketones with a low-lying $\pi\pi^*$ triplet excited state do not undergo this reaction, since this type of triplet does not behave as an alkoxy radical.

The alkyl/ketyl radical pairs generated in the intermolecular reactions undergo the typical reactions of radicals, such as homo- and heterocoupling

Scheme 16

recombination, as well as disproportionation (Scheme 17a). In addition, the 1-hydroxy-1,4-biradicals generated by H-abstraction from the γ -position can give rise to (i) cyclobutanols via C–C coupling (Yang reaction), (ii) the starting product via intramolecular disproportionation, and (iii) an enol and an alkene via C–C bond β -cleavage (Norrish II, see Scheme 17b).

The intramolecular disproportionation causes lower reaction quantum yields, but the addition of Lewis bases (alcohols, water, ethers, etc.), capable of forming hydrogen bonds with the hydroxy group of the ketyl radical, makes this undesired reaction less competitive. The fate of Norrish II biradical intermediates strongly depends on stereoelectronic factors, since cleavage requires the overlap between the involved β C–C bond and the p orbitals of the radical centers. Those factors that disfavor this process make the Yang cyclization a more competitive process. There are two limit conformations for the biradicals, namely, the extended and the gauche conformations. Both intramolecular disproportionation and cyclization require the gauche geometry, whereas fragmentation can occur from both conformations.

Abstraction from the δ -position may happen if no hydrogen atom is available at γ -position

(Scheme 18). Fragmentation of the resulting 1-hydroxy-1,5-biradicals is not a competitive process and, therefore, cyclopentanol is produced. These processes allow application of the Yang reaction to the synthesis of heterocyclic compounds when a heteroatom is present at the δ -position. In addition, H-abstraction can also occur from the β -position, giving rise to 1-hydroxy-1,3-biradicals.

Hydrogen abstraction can also occur at remote positions, and thus the Yang-like cyclization has been used in drug–biomolecules studies,⁴⁶ such as in ketoprofen–cholesterol dyads. This has also been applied with synthetic purposes, for example, in the regio- and stereoselective formation of macrocycles.^{47,48}

Moreover, the C–O bond formation in the course of the Norrish–Yang reaction has also been described in α -mesyloxy- β -keto amides (Scheme 19). Abstraction from the δ -position is followed by a fast loss of methanesulfonic acid to give enolate biradicals. This provides a regioselective cyclization of α -mesyloxy- β -keto amides to 3,4-dihydro-2H-1,3-oxazin-4-ones.

An interesting synthetic application of the intermolecular version is the benzophenone-photosensitized addition of radicals to unsaturated substrates, such as the amidation of α,β -unsaturated

Scheme 17

Scheme 18

Scheme 19

Scheme 20

Scheme 21

esters with formamide.⁴⁹ This strategy has been successfully applied to the synthesis of 1,4-diketones; the radical generated after H-abstraction from 2-alkyl-1,3-dioxolanes by benzophenone efficiently adds to α,β -unsaturated ketones (mainly cyclic enones), eventually leading to 1,4-diketones (Scheme 20).

In addition, *O*-stabilized alkyl radicals undergo addition to chiral α -(arylsulfinyl) enones with high diastereoselectivity (Scheme 21).⁵⁰ This strategy can be used for the synthesis of chiral 3-alkylcyclopentanones and 4-alkyl-2-pentanones, owing to the easy removal of the sulfinyl group.

Moreover, the intermolecular H-abstraction reaction has been used as a strategy for the photo-removal of protecting groups. Thus, 1-oxoindan-2-yl and 1,3-dioxoindan-2-yl groups have been shown to be adequate as photoremovable protecting groups of carboxylic acids in the presence of high concentration of hydrogen donors (Scheme 22).⁵¹ The use of 1,3-diones can be beneficial, mainly in the presence of other potentially photolabile groups, owing to their improved absorption properties.

Scheme 22

H-Abstraction by Quinones

The photo-Friedel–Crafts reaction is one of the methods of photoinduced acylations.⁵² It is based on the hydrogen abstraction from aliphatic and aromatic aldehydes by the 1,4-quinone triplet excited state to generate a radical pair, which combines within the solvent cage⁵³ and/or escapes (Scheme 23). In the latter case, the free acyl radical can subsequently add to a second quinone in a free radical chain reaction.⁵⁴ The operating mechanism depends on the specific reaction conditions. The photoproduct, an acylated hydroquinone, can then be oxidized, leading to the corresponding acylated quinone.⁵⁵ This reaction

Scheme 23

can be performed on a large scale as demonstrated by Mattay *et al.* in the photoinduced acylation of 1,4-quinone and 1,4-naphthoquinone with aliphatic and aromatic aldehydes using sunlight.^{56,57} Moreover, the photo-Friedel–Crafts acylation of 1,4-naphthoquinone with various aldehydes has been performed at room temperature in ionic liquids,⁵³ leading to high conversions and selectivities. This methodology avoids the use of hazardous solvents, such as benzene and acetonitrile, which are commonly used for this transformation, and has been applied in the preparation of heteroacylhydroquinones, with a high yield under sunlight.⁵⁸

2.2 Radical Addition

The X–Y homolytic cleavage of several substrates followed by addition of the resulting radicals to unsaturated compounds can be a useful strategy for the generation of alkyl radicals. Subsequent trapping by hydrogen (Bu_3SnH), chlorine (Cl-CCl_3), bromine (Br-CCl_3), or iodine ($\text{I-C}_4\text{F}_9$, $\text{I-C(CH}_3)_2\text{CO}_2\text{Et}$) atom donors affords β -functionalized oxacycles, which can be used as building blocks for further reactions.

Thus, as mentioned earlier, alkoxyl radicals can be generated by means of N–O α -cleavage of

Scheme 24

Scheme 25

N-alkoxy compounds; then, these radicals can undergo addition to olefinic π -bonds, which has been applied to the synthesis of substituted oxacycles (Scheme 24). The 5-exo-trig-cyclization is the most studied O-radical addition reaction, which proceeds under kinetic control. Similarly, the photochemical S–O α -cleavage of sulfenates with an appended olefinic chain can lead to tetrahydrofurans in the presence of Bu_3SnH .

Moreover, the visible light-absorbing diphenyl ditelluride ($PhTeTePh$) can be used for a smooth photo-thiotelluration of isocyanides in the presence of diphenyl disulphide ($PhSSPh$).⁵⁹ This reaction has been applied to the radical cyclization of *ortho*-vinyl and *ortho*-allyl substituted phenylisocyanides and leads to the formation of bithiolated indole and quinoline derivatives, respectively, in moderate yields (see **Unusual Radical Acceptors**) (Scheme 25).

3 ELECTRON-TRANSFER PROCESSES

Photoinduced electron transfer (PET) reactions have been extensively applied as an interesting route in synthetic organic photochemistry. Light excitation is an adequate strategy for generating radical ions in solution, since molecules are

more easily reduced and oxidized in the excited state. Carbonyl chromophores (ketones, aldehydes, quinones, amides, imides) and aromatic compounds with electron-withdrawing groups (aromatic nitriles, pyridinium, and pyrylium salts) are strong electron acceptors in their excited states and can oxidize substrates such as alkenes, aromatic compounds, amines, thioethers, and carboxylates, among others. In addition, other excited states, such as aromatic compounds with electron-donating groups, can act as reductants. The generated radical cation (radical anion) can act as a secondary electron acceptor (electron donor) in a photocatalytic process; in addition, it can combine with a nucleophilic (electrophilic) species or eliminate an electrophilic (nucleophilic) species to generate radical intermediates.

3.1 Oxidation Followed by Coupling with Nucleophiles

3.1.1 Photosensitized Alkylation of Alkenes

A light-absorbing compound may act as an electron acceptor and play the role of a photosensitizer.⁶⁰ PET from alkenes or dienes to the singlet excited state of the photosensitizer affords radical cations,

Scheme 26

which have to escape from the solvent cage to avoid coupling to the photosensitizer radical anion (Scheme 26). The substrate radical cation reacts with the anion of an active methylene compound (the nucleophile) to form radical intermediates. Back electron transfer from the photosensitizer radical anion followed by protonation produces the anti-Markovnikov adduct of the mono-olefin. In the case of the dienes, the allylic radical dimerizes. Single electron transfer (SET) from the nucleophile is a competitive reaction, but it represents a minor reaction when the nucleophile concentration is maintained low by using a weak base. These reactions represent a green strategy for C–C bond formation, since they require weak bases, such as alkaline metal carbonates, they occur at room temperature, and they do not use noble metals or halogens.

3.2 Reduction Followed by Coupling with Electrophiles

3.2.1 Addition of Ketyl Radicals to Alkenes

PET from tertiary amines to acetophenones and nonaromatic ketones followed by proton transfer

leads to α -aminoalkyl/ketyl radical pairs.⁶¹ The nucleophilic ketyl radical can add to electron-deficient alkenes, such as furanones, in a stereoselective manner (see **Synthetic Radical Photochemistry**).

3.3 Inter- and Intramolecular Electron Transfer Followed by Elimination or Addition of a Neutral Species

3.3.1 Phthalimides

The phthalimide chromophore (reduction potential circa -1.4 V vs the saturated calomel electrode (SCE) in dimethylformamide (DMF) is a strong electron acceptor in the singlet and triplet excited states that can oxidize tethered carboxylate, thioether, and alkene groups, in carboxyalkyl-, thioalkyl-, and alkenyl-*N*-substituted derivatives, respectively. Subsequent protonation of the phthalimide anion and loss of a charged (proton, trimethylsilylmethyl cation) or a neutral (CO_2) electrophilic species generates a biradical, which eventually recombines to a cyclic compound (Scheme 27). The removal of a charged species

Scheme 27

Scheme 28

from the radical ion is termed *mesolytic cleavage* and this type of reactions will be discussed in Section 3.4.

Oxidation of the tethered carboxylate in carboxyalkyl-*N*-substituted derivatives leads to an acyloxy radical in addition to the phthalimide ketyl anion. This process is followed by the loss of CO₂ and protonation of the ketyl anion by the solvent to generate a biradical that recombines (Scheme 27b). Remarkable chiral memory has been detected in triplet-photosensitized reactions such as that shown in Scheme 28, where the radical generated after decarboxylation cyclizes to a pyrrolobenzodiazepine with 86% ee.⁶²

In addition, styrylalkyl-*N*-substituted phthalimides undergo medium- to macro-ring photocyclization via electron transfer between the arylalkenyl and the imide moieties separated by 6–13 bonds (Scheme 27c). This reaction occurs with solvent (methanol) incorporation to the double bond.⁶³ Similar intermolecular reactions have been observed for phthalimides with various olefins.

Mechanistic studies of sulfur-substituted *N*-alkylphthalimides have been performed using time-resolved UV–Vis spectroscopy. The low quantum yield of the cyclization is in accordance with the photoinduced charge separation occurring not in the phthalimide low-lying $\pi\pi^*$ excited state but in the spectroscopically undetectable higher lying $n\pi^*$ state.⁶⁴

3.4 Mesolytic X–Y Bond Cleavage

PET between neutral donors and acceptors leads to the generation of radical ion pairs. The unimolecular cleavage of radical ions into a radical and an

ionic species is termed *mesolytic cleavage*.⁶⁵ Photoinduced SET followed by radical cation fragmentation is a mild and selective strategy for generating radicals from neutral substrates. It has been demonstrated that the more difficult it is to oxidize a substrate, the more energy is accumulated in the radical cation, and therefore the bond cleaves more easily. Thus, fragmentation of strong σ bonds (C–C, C–H, C–Si) can be achieved. The preferred fragmentation can be predicted taking into account the electrofugacity of the leaving cation.⁶⁶

In the case of radical anions, their reactivity depends on the nature of the acceptor. Though, the number of examples of the applicability of radical anions to the generation of organic radicals is fewer than that of radical cations, there are interesting reports on their potential in selective organic synthesis. Some examples are presented in the following sections.

3.4.1 C–H Mesolytic Cleavage

Radical Addition of Tertiary Amines to Alkenes

PET from tertiary cyclic amines to electron-donor-substituted aromatic ketones (photocatalysts) leads to amine radical cations, which after loss of a proton, produce alkyl radicals (Scheme 29).⁶⁷ The nucleophilic character of alkyl radicals permits their trapping by electron-withdrawing substituted alkenes (unsaturated nitriles, esters, lactones, and ketones). The reaction has been carried out in gram scale and applied to asymmetric synthesis using enantiomerically pure 2-(5*H*)-furanones. In addition, in the presence of thiocarbonyl compounds, this strategy has been successfully applied to the addition of acyclic amines to alkenes. Moreover, in the presence

Scheme 29

of cyclic amines with a pendant unsaturated chain, a radical tandem addition–cyclization reaction has been used in the preparation of bicyclic and tricyclic derivatives. An intramolecular version of this reaction in the presence of a chiral sensitizer has also been reported.⁶⁸

3.4.2 C–Si Mesolytic Cleavage

N-Phthalimides linked to a polydonor chain, which contain C-terminal α -amidotrimethylsilyl groups, undergo macrocyclization reactions via sequential SET processes.^{69,70} Thus, electron transfer from the neighboring donor to the excited phthalimide chromophore leads to a radical cation generating an intermediate zwitterionic biradical. Intrachain SET would produce mixtures of interconverting zwitterionic biradicals, a process that

is fast when the polydonor radical cations have similar energies. Finally, hole migration to the α -amidotrimethylsilane center is followed by fast desilylation to form a $1,\omega$ -biradical intermediate, which recombines to the macrocyclic peptide (Scheme 30). Evidence for the involvement of SET processes in linked acceptor–polydonor systems has been found by means of pico- and nanosecond transient absorption measurements in naphthalimide–phenothiazine dyads.⁷¹ In addition, comparison between the photocyclization reactions in phthalimides and 2,3-naphthalimides linked to (trimethylsilyl)methyl ether donors via polyethylenoxy versus polymethylene chains has shown the higher chemical yields and quantum efficiencies of the polyethylenoxy-tethered substrates. This reaction has been applied to the preparation of crown ethers or cyclic oligopeptides. In general, medium- to macrocycles are accessible by this method.^{63,72}

Scheme 30

3.4.3 C–C Mesolytic Cleavage

Mesolytic C–C bond cleavage (Scheme 31) is easier in carbocyclic compounds, where strain release provides the driving force for bond scission. In addition, unstrained C–C bond cleavage can occur mostly in aromatic substrates with aliphatic side chains. The presence of alkyl, aryl, hydroxyl, alkoxy, and siloxy groups at the α -position of the C–C bond lowers the barrier to the mesolytic cleavage, owing to the stabilization of the resulting cation via electron donation.⁶⁶ Deprotonation can be a competitive process to the C–C bond rupture in heteroatom-centered $\text{C}_\beta\text{--C}_\alpha\text{--X}^+$ radical cations, since removal of an electron from the heteroatom lone pair reduces the bond order of the geminal bonds (C–C, C–H, etc.).

In this reaction, radicals are generated in the presence of radical anions, and the cross-coupling can be fast. Thus, in the case of aromatic nitriles as photosensitizers, the radical anions are persistent and non-nucleophilic; as a consequence, they can further react with the radicals arising after the mesolytic cleavage. This results in an unconventional strategy for aromatic alkylation or formation of alkylidihydro derivatives.⁷³

Pinacols derived from benzophenones bearing dimethylamino substituents undergo C–C fragmentation via PET with chloroform followed by mesolytic C–C cleavage.⁷⁴ The fast dechlorination of the chloroform radical anion inhibits the back electron-transfer reaction (radical anion to radical cation)⁷⁵ and makes pinacol fragmentation feasible.

Scheme 31

3.4.4 O-Si Mesolytic Cleavage

Electron-rich double bonds such as silyl enol ethers are easily oxidized by the excited state of electron-deficient aromatic compounds (dicyanoanthracene or dicyanonaphthalene). Cyclization reactions of the initially formed silyloxy radical cation in cyclic silyl enol ethers tethered to an olefinic or an electron-rich aromatic ring can produce bicyclic and tricyclic ketones (Scheme 32).^{76,77} The desilylation

step can occur before or after the cyclization step.⁷⁸

3.4.5 C-Halogen Mesolytic Cleavage

Photoelectron transfer to the σ^* orbital of a carbon-halogen bond leads to σ -radical anions, which subsequently undergo mesolytic fragmentation to produce radicals and halide anions.

Scheme 32

Scheme 33

Aromatic α -Chloroacetamides

The acetamide group can act as electron acceptor versus an appended excited aromatic moiety (Scheme 33).^{79–81} This step is followed by loss of the chloride ion to give an electrophilic alkyl

radical, which reacts with the aromatic ring and eventually leads to the aromatic substitution product. This reaction has been applied to the preparation of azepine derivatives, which are not easily accessible by ground state reactions.

Scheme 34

α -Iodo Enones

PET from triethylamine to α -iodo enones bearing an alkynyl moiety easily affords cyclization products in yields ranging from 50% to 75%, via the α -enone radical generated from mesolytic cleavage of the C–I bond (Scheme 34).⁸²

Electron Transfer to Chloroaromatics

Inter- or intramolecular electron transfer from amines to chloroaromatics, followed by mesolytic cleavage of the C–Cl bond, leads to aromatic radicals, which abstract a hydrogen atom from the medium.⁸³ Redox photosensitization has been used to reduce polychlorobenzenes with electron-donor photosensitizers such as *N, N, N', N'*-tetramethyl-*para*-phenylenediamine and 2-methoxyphenol.⁸⁴ However, when a chloropyridine residue is attached to an enaminone, mesolytic cleavage of the C–Cl bond leads to pyridyl radicals, which can proceed to cyclization products (Scheme 35).⁸⁵

3.4.6 C–Se Mesolytic Cleavage

Reductive activation of carbon–selenium bonds in $\text{R}_2\text{CH–SePh}$ compounds can be photosensitized by electron-rich aromatic compounds, such as

Scheme 36

dimethoxynaphthalenes, in the presence of ascorbic acid as co-oxidant. The C–Se radical anions cleave to the carbon-centered radicals and PhSe radical.⁸⁶ This strategy has shown applicability as in the unimolecular phenylselenenyl group transfer reactions shown in Scheme 36.

3.4.7 Se–Se and Si–Se Mesolytic Cleavage

An interesting alternative to the use of hydride reagents to initiate radical additions is that of one-electron reductive PET activation of Se–Se and Si–Se bonds of PhSe–SePh and PhSe–SiR₃ seleno-organic compounds, respectively (Scheme 37). This bond activation is performed by using electron-rich aromatic photosensitizers, such as 1,3-dimethoxynaphthalene and dimethoxyanthracene, in the presence of ascorbic acid as the sacrificial electron donor.⁸⁷ In the case of PhSe–SiR₃, trialkylsilyl

Scheme 35

Scheme 37

radicals are generated; the alkylsilyl radical is more halophilic than alkyl- or aryl-substituted tin radical.

Moreover, taking into account the high rate constant ($9.6 \times 10^7 \text{ M}^{-1} \text{ s}^{-1}$) for the reaction of R₃Si radical with alkyl phenylselenides and the fast oxidative dimerization of PhSe anion to PhSe-SePh, a catalytic strategy for phenylselenenyl group transfer-based radical reaction has been developed from seleno-organic compounds as precursors.⁸⁸ The generality of the reaction has been demonstrated by carrying out model cyclizations, intermolecular additions, and tandem annulations.

3.4.8 N-S Mesolytic Cleavage

The N-S bond of *N*-tosyl amides undergoes cleavage after PET from 2-phenyl-*N*, *N*'-dimethylbenzimidazole to the amide, owing to the remarkable weakening of the N-S bond in the radical anion. This is a simple, mild, and chemoselective desulfonylation of *N*-tosyl amides.⁸⁹

4 SPECIAL TECHNIQUES FOR THE CHARACTERIZATION OF PHOTOCHEMICALLY GENERATED RADICALS

4.1 Flash Photolysis Spectroscopy

Throughout this chapter, we have mentioned examples in which the flash photolysis technique has been applied in the detection of radicals generated after irradiation of different types of substrates.⁹⁰ It uses a short and intense flash of light (pump source), often from a laser, to generate the reactive species in high concentration, allowing spectroscopic detection. The absorption changes can be recorded, for example, using a spectrally continuous xenon lamp (probe source). Probe sources in a pulsed mode can be used to enhance the photon flux for measurements in short-time ranges.

Both spectral and kinetic data can be obtained; in the spectral mode, complete transient absorption spectra are measured at a specific time after excitation using a time-gated array detector. In the kinetic mode, the transient absorption, generated by the light pulse, is recorded at a given wavelength as a function of time by using a photodetector and a digital storage oscilloscope. In general, transient absorption features can be measured with temporal resolutions from picoseconds to milliseconds in pulsed mode, and milliseconds to seconds in continuous mode.

In addition, the application of the *two-photon two-color laser flash photolysis* to study the photoreactivity of photogenerated radicals has been mentioned above. A first laser pulse (referred to as *synthesis* laser) produces the radical, whereas the second laser pulse from the *photolysis* laser excites it.⁹¹ The wavelength of the photolysis laser is selected so as to match the optical absorption of the radical.

In laser flash photolysis, a problem may arise when the photogenerated radicals do not absorb in the available analyzing wavelength range so as to be optically detected. This problem can be circumvented by using other time-resolved detection techniques, such as *time-resolved infrared (IR) spectroscopy*. This technique also uses a pump-probe methodology; the pump pulse is often generated by a pulsed laser, whereas the probe beam is in the IR region. Thus, alkoxycarbonyl radicals generated after laser excitation can be characterized in this way, monitoring the characteristic highly intense carbonyl stretching bands.⁹²

4.2 Other Spectroscopic Techniques

Photoacoustic Spectroscopy

Photoacoustic spectroscopy is based on the monitoring of heat evolved from nonradiative deactivation of the transient species obtained after the excitation of an absorbing molecule.⁹³ The rapid nonradiative relaxation of the generated transient species causes a local heating in the medium. This causes a density change of the solvent, inducing a change in the refractive index, which leads to a thermal wave monitored by a probe laser. Intersystem crossing, internal conversion, and photochemical reactions are detectable with this technique, which can provide important kinetic and thermodynamic information on metastable species produced directly or indirectly in the system and can be of particular interest for the study of nonoptically detectable species. Regarding radicals, photoacoustic spectroscopy has allowed the determination of the enthalpy of formation of the benzophenone ketyl radical from the reaction of the benzophenone triplet excited state and benzydrol. In addition, it has been applied to the determination of the α (C–H) bond dissociation energy of amines by monitoring the H-abstraction by triplet benzophenone.

Time-Resolved Fluorescence Spectroscopy

Time-resolved fluorescence spectroscopy of radicals is also a useful tool in radical research. Thus, a radical can be generated after a laser pulse and its emission can be measured after excitation with a second pulse. In the *time-resolved IR emission spectroscopy*, the precursor molecule dissociates upon irradiation, and the transient radical is generated

with high vibrational excitation; IR emission of these excited species is then detected.⁹⁴

Photochemically Induced Dynamic Nuclear Polarization (photo-CIDNP) Technique

Photochemically induced dynamic nuclear polarization (photo-CIDNP) technique holds all the advantages of NMR spectroscopy and in addition allows the analysis of processes occurring in a nanosecond timescale.⁹⁵ It is a powerful tool for the study of radical cage reactions. When radical pairs are formed by excitation of a molecule, they are spin correlated. The population of energy levels is not at thermal equilibrium and electron spin transitions may be fully polarized. Part of the polarization is transferred to nuclear spins via the hyperfine interaction, which leads to strong absorption or emission signals. Transient free radicals⁹⁶ have been characterized, and their reaction mechanisms studied using this powerful technique.

Thus, it has been used to confirm the radical nature of the photo-Fries rearrangement.⁹⁷ In addition, the absence of polarization in the photolysis of 1-naphthyl acetate protons indicates an insignificant recombination of the naphthoxyl and acyl radicals to the initial compound and, hence, that recombination is not responsible for the difference from unity of the quantum yield of this rearrangement. In agreement, flash photolysis experiments show formation of the 1-naphthyl acetate triplet excited state, whose main deactivation channel is the triplet–triplet annihilation.

5 CONCLUSION

A wide variety of organic radicals can be photochemically generated from suitable precursors. These reactive intermediates may follow different secondary pathways, giving rise to a vast array of photoproducts. Hence, photoinduced radical reactions may be of preparative interest, provided that the product yields and selectivities are sufficient. A large body of experimental mechanistic evidence has been obtained by laser flash photolysis or related time-resolved techniques; this constitutes a valuable contribution to the field of physical organic chemistry.

Radiation-Induced Radical Reactions

Krzysztof Bobrowski

Institute of Nuclear Chemistry and Technology, Warszawa, Poland

1 INTRODUCTION

Radiolysis, the initiation of reactions by high-energy radiation, is a very valuable and powerful chemical tool for inducing and studying radical reactions in gases, liquids, and solids. The chemical changes that commonly involve radiation-induced radical reactions are the consequences of the absorption of the energy of high-energy radiation by matter.^{1–7} The mechanisms by which the radiation energy is deposited in matter depend on the type of radiation. There are three types of ionizing radiations: (i) charged particles (electrons and heavy positive ions), (ii) neutral particles (neutrons), and (iii) electromagnetic radiation (X- and γ -rays). The mode of interaction of the three classes of ionizing radiation with matter is summarized in Scheme 1.

The relative importance of these three main processes, that is, emission of radiation “bremsstrahlung,” and inelastic and elastic collisions by which charged particles interact with matter, depends on the energy of the particles and also on the nature of the material they passed through. Only the first two of them reduce the energy of the particle and give rise to ionization and excitation of the medium. In the case of neutrons, there are four main processes by which they interact in collisions with atomic nuclei: elastic and inelastic scatterings, nuclear reactions, and capture. γ -Rays are produced by inelastic scatterings and capture. Protons and other positive ions are produced by elastic scattering and nuclear reactions. There are three important processes by which electromagnetic

radiation interacts with matter. These processes are the photoelectric and Compton effects, pair production whose probabilities varied with the energy of radiation, and the atomic number Z of the material involved.^{1–7}

As the overall effects of all three types of high-energy radiation are ionization and excitation of the molecules of the medium through which they pass, the chemical effects of the various high-energy radiation are qualitatively similar. These processes may be generally represented by the following equations:

where M is a molecule of the absorbing medium and M^+ and M^* are the ionized state and the excited state of the molecule, respectively. The symbol “ $\xrightarrow{\text{high-energy radiation}}$ ” used informs that a reaction is initiated directly by a high-energy radiation. The electrons produced in ionization (1) can cause further ionization and excitation. Thus, the primary effect of any type of ionizing radiation on matter is the production of ions, excited states, and electrons. These species subsequently react in a number of ways leading to the production of free radicals.

Radiation energy deposition is spatially inhomogeneous and creates sites of dense ionization, called *spurs*. The mean rate of energy loss by the particle per unit path length, called *linear energy transfer* (LET), increases in the sequence electron, proton, and α -particle, for the same particle energy (E). This is, according to the Bethe equations,³ because

Scheme 1 Interaction of high-energy electromagnetic radiation, neutrons, and charged particles with matter.

the value of LET increases with decreasing particle velocity (v), which decreases with increasing particle mass M for the same E and because LET increases as the square of the particle charge Z . The average distance between *spurs* along a track can be roughly calculated as 10^2 eV/LET . Considering particles with $E = 10 \text{ MeV}$, ~ 500 , 12, and 1 nm distances between spurs along electron, proton, and α -particle tracks are obtained, respectively. At subpicoseconds time scales, local inhomogeneous distribution of ions, excited states, and electrons in *spurs* produced by high-energy electromagnetic radiation or by the charged particles (including electrons) results in high local concentration of reactive species promoting their geminate recombination. Inhomogeneity of such type does not take place in photolytic methods, where photolysis generates excitations and in some cases ionizations, with a spatial distribution determined by the distribution of the absorbing species (solute) (see **Photo Induced Radical Reactions**).⁸

An important feature of high-energy radiation is that it is absorbed in matter nonselectively, which means that molecules are ionized according to their relative abundance in the medium irradiated. In another words, for both high-energy photons and high-energy charged particles, partition of energy among the components of a sample is controlled by the contribution of each component to the density of electrons. This leads to the concept of a *direct effect* of the radiation on the solute and an *indirect effect*, in which excited species and ions derived from the solvent subsequently react with the solute. Therefore, in studies on dilute solutions, it is the solvent that absorbs most of the energy. Any direct effect on the solute molecules will be negligible in comparison with the indirect effect. The radical reactions observed will be essentially

those resulting from the interactions of excited states and/or ions from the solvent with themselves or with any solute that is present. Therefore, the knowledge of the radiolysis mechanism of the solvent is of paramount importance for radical reactions initiated by high-energy radiation. One potential disadvantage of the latter situation is that the limiting rate of intermediate formation derived from the solute is usually controlled by its concentration. In photolysis, the energy of quanta is transferred directly to the chromophore producing radical intermediates directly. On the other hand, high-energy radiation allows studies on radical reactions that cannot be studied by photochemistry, due to differences in the fundamental physical processes connected with absorption of energy. For instance, absorption of high-energy radiation permits initiation of radical reactions in systems that do not contain a chromophore or an excited state that would be amenable to photolytic methods. High background absorption of the system, low quantum yields, or the lack of suitable photosensitizers also limits the application of photolytic techniques to initiate certain radical reactions.⁸

Two main types of approaches are commonly used in applying high-energy radiation for inducing radical reactions. First, radiolysis can involve exposure to a steady radiation source, usually a ^{60}Co source for a desired amount of time, and the stable products resulting from the radical reactions are analyzed after the end of the radiolysis period. Modern analytical techniques are necessary to measure and identify the products. These include high-performance liquid chromatography for separation of products, with spectrophotometric, fluorescence, electrochemical, mass spectrometric, or nuclear magnetic resonance (NMR) detections as appropriate. The second approach is required

where it is desired to generate sufficient concentration of radicals in a short time to follow radical reactions directly. This technique, pulse radiolysis, has been the main source of quantitative information concerning reaction kinetics of free radicals in solutions.^{9–13} For radicals in solutions, the most commonly used technique is time-resolved UV-vis spectroscopy,^{11,12,14} but time-resolved conductivity,^{12,15–17} electron paramagnetic resonance,¹⁸ vibrational resonance Raman spectroscopy,¹⁹ microwave absorption spectroscopy,^{20,21} polarography,²² circular dichroism,²³ and very recently infrared spectroscopy,^{24,25} although less widely employed, can and do provide kinetic, spectral, and mechanistic details that are not accessible via optical measurements.

The above introduction is supposed to serve as a brief summary of specific features of high-energy radiation and its interaction with matter for those researchers who are new to the field of radiation chemistry. Owing to space limitations, a comprehensive overview of basics of radiation-induced phenomena cannot be given here. There are many excellent and comprehensive chapters in books^{1,4,6,26–28} and books,^{2,5,7,29–33} which present and discuss the topics above in a more detailed manner.

2 RADIATION-INDUCED RADICAL REACTIONS IN GASES

2.1 Basic Considerations

Radiolysis of gases differs from radiolysis of the condensed phases because of differences in the electron density of the absorbing medium and variations in the related freedom of the excited and ionized species. For the above reasons, the transient species diffuse faster, have longer lifetimes, and therefore the track effects are less important. Radiation chemical yields of transients are less dependent on the LET of radiation and their distribution is more uniform in gases than in liquids and solids.

The radiolysis of a simple gas generates many primary products, including excited states, positive ions, and low-energy electrons. These processes may be visualized by (1 and 2) (*vide supra*). The resulting positive ions and electrons recombine rapidly to produce neutral species with very high internal energy (molecular or atomic). They

can subsequently undergo rapid decomposition generating free radicals (3) or transfer their excess energy to other species in the gas mixture (4), which then undergo decomposition to give radicals (5), respectively:

The literature concerned with radiation-induced radical reactions in gas phase is extensive. A full account of this topic is outside the scope of this article. A few systems only can be presented here to illustrate the different types of reactions observed for different molecules. Therefore, the reader is referred to several excellent reviews, which address them in more details (see **Radical Chemistry in the Gas Phase**).^{34–37}

2.2 Selected Gaseous Systems

Generally, high yields of radicals can be obtained by irradiation of various bath gases, including hydrogen (H₂), ammonia (NH₃), nitrous oxide (N₂O), H₂O (in form of water vapor), sulfur hexafluoride (SF₆), halogenated hydrocarbons, and noble gases with additives.

2.2.1 Hydrogen and Hydrogen/Chlorine Systems

The radiation-induced reactions in gaseous hydrogen can be summarized by the following reactions: ionization (6), excitation and dissociation (7), ion molecule reaction (8), and neutralization-decomposition (9)²:

Once the main radical product (H[·]) is formed, in the presence of small amounts of additives in the bath gas, it can be used to produce other

radicals. Using such systems, a variety of free radical reactions have been studied.

For example, in presence of oxygen (O_2), formation of $HO_2^{\cdot}$ was observed:

Moreover, it was found that the gas-phase self-reaction of $HO_2^{\cdot}$ radicals (11) was markedly enhanced in the presence of NH_3 and H_2O ^{38,39}:

This phenomenon was rationalized in terms of the formation of hydrogen-bonded transient complexes between the $HO_2^{\cdot}$ and NH_3 or H_2O ³⁸:

Irradiation of gaseous hydrogen (H_2) and chlorine (Cl_2) mixture is a good example, where formation of hydrogen chloride occurs via chain reactions where chlorine and hydrogen atoms take part in the propagation step:

2.2.2 Ammonia

The primary processes that should be considered in mechanisms for radiolysis of gaseous ammonia are ionization and excitation⁴⁰:

There is considerable experimental support that ions and excited molecules produced in reactions (17)–(21) lead principally to $^{\cdot}NH_2$ and $^{\cdot}H$

atoms (21–24):

Since the relative importance of various elementary processes involved in radiolysis of gaseous NH_3 depends on dose rate, temperature, and pressure, it is not possible to formulate a mechanism that will be applicable under all conditions.

2.2.3 Water Vapor

Primary ionization processes in water vapor can be described by the following ionization reactions³⁵:

The primary radicals produced ($^{\cdot}H$ and $^{\cdot}OH$) in the source reactions (26 and 27) can react with a wide range of molecules to produce secondary radicals.^{35,37} For example, in the presence of olefinic (e.g., C_2H_4) and hydrogen atom-donating scavengers (e.g., CH_3OH and HBr), the alkyl (30) and hydroxyalkyl radicals (31–33) and bromine atoms (34 and 35) can be formed:

The reaction of $^{\cdot}OH$ radicals with ethylene (32) represents interesting mechanistic case. The results revealed three kinetically separate temperature

regions: 343–563 K, where the disappearance of $\cdot\text{OH}$ radicals is dominated by the addition of $\cdot\text{OH}$ radicals to the double bond of ethylene (32a); 563–748 K, where concurrent reactions of addition, the reverse reaction of addition (32b), and H-atom abstraction are dominant (32c); and 748–1173 K, where H-atom abstraction is likely the main reaction (32c).⁴¹

2.2.4 Sulfur Hexafluoride (SF_6)

Irradiation of gaseous sulfur hexafluoride (SF_6) enables production of radicals ($\cdot\text{F}$ atoms and sulfur pentafluoride radicals $\cdot\text{SF}_5$) (36–39). The former radicals ($\cdot\text{F}$) are very difficult to make via other techniques:

$\cdot\text{F}$ atoms produced in reactions (37) and (38) are capable of abstracting H atoms from alkanes (RH) and halogenated hydrocarbons ($\text{R}^{\text{X}}\text{H}$) forming alkyl ($\cdot\text{R}$) and halogenated alkyl ($\cdot\text{R}^{\text{X}}$) radicals, respectively (40 and 41)^{42–47}:

where $\text{X}=\text{Cl}, \text{Br}, \text{I}, \text{and F}$. In the presence of oxygen, this system enables easy generation of peroxy radicals:

Since peroxy radicals ($\text{RO}_2\cdot/\text{R}^{\text{X}}\text{O}_2\cdot$) play a key role in the chemistry occurring in the atmosphere, their reactions with $\cdot\text{NO}$ and $\cdot\text{NO}_2$ (43 and 44)

are of great importance and have been extensively studied using pulse radiolysis technique by several groups.^{47–66} $\text{RO}_2\cdot$ and $\text{R}^{\text{X}}\text{O}_2\cdot$ reactions with $\cdot\text{NO}$ and $\cdot\text{NO}_2$ constitute a reliable data bank of rate constants and activation energies for environmental studies:

The reactions (43a and 43b) involve a short-lived complex, which can either decompose (43a) or rearrange to the nitrate (43b).⁶⁴ It was found that the reactivity increased with the degree of halogenation on the carbon atom attached to the $\text{OO}\cdot$ group and decreased with increasing size of the peroxy radical.^{48,55} There was little or no effect of β -halogenation to the $\text{OO}\cdot$ group on reactivity.⁶⁴

Reaction (44) is complex, with the initial formation of an excited adduct, which can either decompose back to the reactants or be deactivated by collision with a “third body”.⁶⁴

2.2.5 Halogenated Hydrocarbons

Halogenated hydrocarbons reacting with thermal electrons undergo dissociative electron attachment forming respective halogenated hydrocarbon radicals via temporary excited negative ions^{37,67}:

Studies on the electron attachment to halogenated hydrocarbons demonstrated the extreme fragility of these compounds toward low-energy electrons. The rate constants of thermal electron attachment increase in the order $\text{F} < \text{Cl} < \text{Br} < \text{I}$ and with the number of halogen atoms in the molecule.⁶⁸

2.2.6 Argon (Ar) Mixtures

A large number of radiation-induced radical reactions have been studied in gaseous Ar mixtures. For example, the radiolysis of Ar/aromatic hydrocarbon mixtures produces excited metastable argon atoms (49), which on collision with benzene (50) or toluene^{69–72} (51) generate phenyl or benzyl radicals, respectively:

Using these systems, the recombination reactions of phenyl/benzyl radicals (52 and 53) and of monosubstituted benzenes (54)⁷⁰ with hydrogen atoms and of phenyl radicals with nitric oxide (NO) (55) have been studied:

The rate constants for the reaction (54) were correlated with the Hammett σ -values of the X-substituents, showing that hydrogen atoms ($\cdot\text{H}$) are electrophilic in these reactions.⁷⁰

The gas-phase pulse radiolysis of argon (Ar)/carbonitridic cyanide (C_2N_2) mixture has been used for the generation of cyanide radicals (49 and 56),

and subsequently to study their reactions with selected alkanes (methane and ethane) (57 and 58) and alkenes (ethylene, propylene, and 1,3-butadiene) (59–61) and benzene (62)⁷³:

The measured rate constants for the reactions (59–62) approach the collisional limit and reflect the extremely electrophilic nature of $\cdot\text{CN}$ radicals.⁷³

The gas-phase radiolysis of argon (Ar)/carbon tetrachloride (CCl_4) mixture has been used as a source of $\cdot\text{CCl}_3$ radicals (49 and 63):

Their reaction with nitric dioxide ($\cdot\text{NO}_2$) has been subsequently studied by following the kinetics of production of CCl_3NO_2 (64)⁷⁴:

3 RADIATION-INDUCED RADICAL REACTIONS IN LIQUIDS

3.1 Radiolysis of Water

3.1.1 Basic Considerations

The radiolysis of water has been studied intensively since the beginning of radiation chemistry. Therefore, water is the most thoroughly characterized solvent as far as the knowledge about the properties of primary radiolysis transients is concerned. Most of the radiation-induced radical reactions have been studied in aqueous solutions because it is relatively easy and convenient to produce enormous variety of highly reactive radical species, which otherwise cannot readily be generated by thermal or photochemical methods. Excellent critical reviews of the spectral and kinetic properties, methods of production, and compilations of reaction rate constants of the primary radiolysis transients with inorganic and organic substrates have been written over the years.^{5,75–89}

The current state of knowledge can be summarized by the following reactions^{88,89}:

Equations (65 and 66) represent ionization and electronic excitation of water molecules, respectively, and these processes occur in $\sim 10^{-16}$ s. The water radical cation (H_2O^+) is a very strong acid and immediately loses a proton (in $\sim 10^{-14}$ s) to neighboring water molecules forming hydroxyl radical ($\cdot\text{OH}$) (67):

The electronically excited water molecules (H_2O^*) undergo homolytic dissociation (68) in $\sim 10^{-13}$ s and the electron ejected in an ionization process (65) undergo, after thermalization, hydration by $\sim 10^{-12}$ s (69):

At this time, for low LET radiation (γ -rays from ^{60}Co source and fast electrons from an accelerator), the products of reactions represented by (67–69) are distributed inhomogeneously and located together in small widely separated *spurs*. Fraction of them interacts with one another within *spurs* forming molecular and secondary radical products. The complete set of spur reactions in water (70–77) together with the respective rate constants is listed in Table 1.^{81,89}

The remaining fraction of primary and secondary products diffuses into the bulk solvent and becomes homogeneously distributed and may react with added solutes (acting as radical scavengers). The spur processes and diffusion of reactants outside *spurs* are completed within $\sim 10^{-7}$ s. For the purposes of this article, the radiolysis of water (for low LET radiation $\sim 0.23 \text{ eV nm}^{-1}$) can be summarized by the following equation⁸⁹:

The numbers in parentheses represent radiation chemical yields (known as G values) in units of $\mu\text{mol J}^{-1}$.

$\cdot\text{H}$ atoms and hydrated electrons (e_{aq}^-) exist in an acid/base equilibrium with $\text{p}K_{\text{a}}(\cdot\text{H}) = 9.1$, and hence, at $\text{pH} < 4$, the diffusion-controlled reaction of e_{aq}^- with bulk protons becomes important ((72) in Table 1) resulting in a pH-dependent increased yield of $\cdot\text{H}$ atoms. On the other hand, in very basic solutions, $\cdot\text{H}$ atoms are converted into e_{aq}^- (79), with $k_{79} = 2.2 \times 10^7 \text{ dm}^3 \text{ mol}^{-1} \text{ s}^{-1}$.⁸³

In basic solutions, $\cdot\text{OH}$ radical is converted to its conjugate base, oxide radical ion ($\text{O}^{\cdot-}$), with $\text{p}K_{\text{a}}(\cdot\text{OH}) = 11.8$ (80), with $k_{80\text{f}} = 1.3 \times 10^{10} \text{ dm}^3 \text{ mol}^{-1} \text{ s}^{-1}$ and $k_{80\text{r}} = 10^8 \text{ dm}^3 \text{ mol}^{-1} \text{ s}^{-1}$.⁹⁰

Redox properties of the primary radicals from water radiolysis can be summarized as follows⁸³: the hydrated electron (e_{aq}^-) is a powerful reductant in neutral and alkaline solutions with a reduction potential of $E^0 = -2.87 \text{ V}$ versus normal hydrogen electrode (NHE). The hydrogen atom ($\cdot\text{H}$) becomes the major reductant in acidic solutions with a reduction potential of $E^0(\text{H}^+/\cdot\text{H}) = -2.31 \text{ V}$ versus NHE. The hydroxyl radical ($\cdot\text{OH}$) is a powerful oxidant with a reduction potential of $E^0(\cdot\text{OH}/\cdot\text{OH}) = 1.90 \text{ V}$ versus NHE in neutral solutions and with a reduction potential of $E^0(\text{H}^+, \cdot\text{OH}/\text{H}_2\text{O}) = 2.72 \text{ V}$ versus NHE in acidic solutions.

Table 1 Spur reactions in water.^{81,89}

Reaction	Number	$k \text{ (dm}^3 \text{ mol}^{-1} \text{ s}^{-1}\text{)}$
$\text{e}_{\text{aq}}^- + \text{e}_{\text{aq}}^- \rightarrow \text{H}_2 + 2\text{OH}^-$	(70)	5.4×10^9
$\text{e}_{\text{aq}}^- + \cdot\text{OH} \rightarrow \text{OH}^-$	(71)	3.0×10^{10}
$\text{e}_{\text{aq}}^- + \text{H}_3\text{O}^+ \rightarrow \cdot\text{H} + \text{H}_2\text{O}$	(72)	2.3×10^{10}
$\text{e}_{\text{aq}}^- + \cdot\text{H} \rightarrow \text{H}_2 + \text{OH}^-$	(73)	2.5×10^{10}
$\cdot\text{H} + \cdot\text{H} \rightarrow \text{H}_2$	(74)	1.3×10^{10}
$\cdot\text{OH} + \cdot\text{OH} \rightarrow \text{H}_2\text{O}_2$	(75)	5.3×10^9
$\cdot\text{OH} + \cdot\text{H} \rightarrow \text{H}_2\text{O}$	(76)	3.2×10^{10}
$\text{H}_3\text{O}^+ + \text{OH}^- \rightarrow 2\text{H}_2\text{O}$	(77)	1.4×10^{11}

3.1.2 Selective Generation of Primary Radicals

The primary radicals formed in the radiolysis of aqueous solutions possess both oxidative ($\cdot\text{OH}$) and reductive (e_{aq}^- , $\cdot\text{H}$) properties. In most cases, it is desirable to study the reactions of individual radicals since interpretation of experiments will be easier

when dealing with only one type of radical. This can be achieved via appropriate chemical additives to design solutions that largely contain a single radical species.⁸⁹

Oxidizing Conditions

In order to study the reactions of $\cdot\text{OH}$ radicals without a contribution of e_{aq}^- , the reaction solution is saturated with nitrous oxide (N_2O). Hydrated electrons are rapidly scavenged by the N_2O generating additional amount of $\cdot\text{OH}$ radicals (81), with $k_{81} = 9.1 \times 10^9 \text{ dm}^3 \text{ mol}^{-1} \text{ s}^{-1}$.⁹¹

The radiation chemical yield of $\cdot\text{OH}$ radicals is thus the sum of the primary yields of $\cdot\text{OH}$ radicals and e_{aq}^- , that is, $0.56 \mu\text{mol J}^{-1}$. The hydrogen atoms react only slowly with N_2O ($k = 2.1 \times 10^6 \text{ dm}^3 \text{ mol}^{-1} \text{ s}^{-1}$).⁸⁹ Therefore, the only other radical present is the $\cdot\text{H}$ atom, which represents $\cong 10\%$ of the total radical yield at neutral solutions.

Reducing Conditions

A good approach to study hydrated electron reactions without a contribution of $\cdot\text{OH}$ radicals is irradiation of Ar/N_2 -saturated aqueous solutions containing high concentration ($>0.1 \text{ M}$) of 2-methyl-2-propanol (*tert*-butanol). The alcohol is added to remove the highly reactive $\cdot\text{OH}$ radical by transferring the radical site to a 2-hydroxy-2,2-dimethylethyl radical (82), with $k_{82} = 6.0 \times 10^8 \text{ dm}^3 \text{ mol}^{-1} \text{ s}^{-1}$.⁸³

Under these experimental conditions, the yield of $\cdot\text{H}$ atoms is almost not affected since their rate constant with 2-methyl-2-propanol is low ($k = 1.7 \times 10^5 \text{ dm}^3 \text{ mol}^{-1} \text{ s}^{-1}$)⁹² and recently revised at $1.15 \times 10^6 \text{ dm}^3 \text{ mol}^{-1} \text{ s}^{-1}$.⁹³ The $\cdot\text{CH}_2(\text{CH}_3)_2\text{C}-\text{OH}$ radical is largely unreactive mostly to steric hindrance. Moreover, its optical absorption spectrum is located to the UV below 270 nm and therefore does not interfere with other radical spectra located at $>270 \text{ nm}$. After removal of $\cdot\text{OH}$ radicals, only e_{aq}^- and H atoms are present, with $G(e_{\text{aq}}^-) = 0.28$ and $G(\cdot\text{H}) = 0.062 \mu\text{mol J}^{-1}$ in neutral solution.

The cleanest way to study $\cdot\text{H}$ atom reactions without the contribution of $\cdot\text{OH}$ radicals is irradiation of acidic aqueous solutions saturated with H_2 . However, due to the low solubility of H_2 under normal pressure conditions, this requires a special pressure cell. The hydroxyl radicals react with H_2 generating additional amount of $\cdot\text{H}$ atoms (83), with $k_{83} = 4.2 \times 10^7 \text{ dm}^3 \text{ mol}^{-1} \text{ s}^{-1}$.⁸³

For the above reason, $\cdot\text{H}$ atom reactions, without contribution of $\cdot\text{OH}$ radicals and hydrated electrons, can be conveniently studied by irradiation of highly acidic Ar/N_2 -saturated aqueous solutions containing high concentration ($>0.1 \text{ M}$) of 2-methyl-2-propanol (*tert*-butanol). The $\cdot\text{OH}$ radicals are removed in reaction (82) and e_{aq}^- are converted to $\cdot\text{H}$ atoms via neutralization with H^+ ((72) in Table 1).

3.1.3 Generation of Selective Secondary Radicals

Oxidizing Radicals

Since the $\cdot\text{OH}$ radical is a very strong oxidant, it reacts very fastly with almost all compounds and thus is not selective. Moreover, in one-electron oxidation reactions, the $\cdot\text{OH}$ radical reacts with formation of a primary intermediate adduct. Therefore, there was a strong need for a generation of more selective radicals that react by a direct electron transfer (ET).^{86,89} In aqueous solutions, a large variety of oxidizing inorganic radicals have been generated and their reaction rates and spectra obtained have been compiled.^{79,84,94}

Reactions leading to generation of the most common oxidizing selective inorganic radicals from the primary $\cdot\text{OH}$ radicals are presented by (84a–93).^{82,84,88}

Hydroxyl radicals react with many halide (pseudohalide) ions forming a three-electron-bonded adduct radicals that further decompose into ${}^-\text{OH}$ and the halide (pseudohalide) radicals (84a–88a). The latter radicals form the weak $\sigma\sigma^* 2c-3e$ bond complexes, dihalogen (pseudohalogen) radical anions, with another halide (pseudohalide) ions (84b–88b).^{95–104} In basic and neutral solutions, $\cdot\text{Cl}$

radical is a stronger oxidant than $\cdot\text{OH}$, and the formation of $\text{Cl}_2^{\cdot-}$ (84b) can only proceed in acidic solutions (84a).⁹⁷

Equilibrium constants of reactions presented by (84b–88b) are compiled in Table 2.

A very useful way of generating oxidizing radicals, particularly when they are more powerful than $\cdot\text{OH}$ in neutral solution (e.g., $\text{SO}_4^{\cdot-}$), is via the following reactions⁸²:

Table 2 Equilibrium constants of selected dimeric radical anions.

Dimeric radical anion	Number	Equilibrium constant K ($\text{dm}^3 \text{mol}^{-1}$)
$\text{Cl}_2^{\cdot-}$	(84b)	6.0×10^4 ¹⁰³ ; 1.4×10^5 ⁸⁸
$\text{Br}_2^{\cdot-}$	(85b)	3.9×10^5 ¹⁰⁴
$\text{I}_2^{\cdot-}$	(86b)	1.1×10^5 ^{95,101}
$\text{N}_6^{\cdot-}$	(87b)	0.33 ¹⁰⁰
$(\text{SCN})_2^{\cdot-}$	(88b)	2.0×10^5 ^{95,102}

Compilation of the reduction potentials of selected oxidizing inorganic radicals formed in reactions (84a)–(95b) is presented in Table 3.

Radiolysis of water provides a very convenient source of one-electron oxidizing radicals characterized by a very broad range of reduction potentials.^{86,105} These radicals are useful for studying redox changes in metalloproteins and organometallic complexes since they more likely attack the metal centers. However, they are particularly useful for studying long-range electron transfer (LRET) processes in biological systems such as synthetic and native peptides and native, mutant or modified proteins since they could selectively attack amino acid residues.^{5,85,106–108}

Reducing Radicals

Since both e_{aq}^- and H atoms are very strong reductants, they do not react in a selective way. Carbon dioxide radical anion ($\text{CO}_2^{\cdot-}$) is an efficient reducing agent, rapidly reducing a large number of aqueous metal ions and metal complexes without formation of intermediate adducts.⁸⁸ Reactions leading to generation of this most common reductive selective inorganic radical from the primary $\cdot\text{OH}$ and $\cdot\text{H}$ radicals are presented by the following equations:

Reduction of O_2 by $\text{CO}_2^{\cdot-}$ is commonly used to produce superoxide radical ions (98) for study of its reactions⁸⁴:

The less negative reduction potential of $\text{CO}_2^{\cdot-}$ relative to that of e_{aq}^- is illustrated by its ability

Table 3 Reduction potentials of selected inorganic radicals.¹⁰⁵

One-electron oxidants		One-electron reductants	
Redox couple	<i>E</i> (V) vs NHE	Redox couple	<i>E</i> (V) vs NHE
SO ₄ ^{•−} /SO ₄ ^{2−}	+2.47		
Cl ₂ ^{•−} /2Cl [−]	+2.30		
Br ₂ ^{•−} /2Br [−]	+1.66		
N ₃ ^{•−} /N ₃ [−]	+1.33	CO ₂ /CO ₂ ^{•−}	−1.90
(SCN) ₂ ^{•−} /2SCN [−]	+1.33	SO ₂ /SO ₂ ^{•−}	−0.28
I ₂ ^{•−} /2I [−]	+1.04		
NO ₂ ^{•−} /NO ₂ [−]	+1.00		
ClO ₂ ^{•−} /ClO ₂ [−]	+0.93		
SO ₃ ^{•−} /SO ₃ ^{2−}	+0.63		

to reduce aromatic compounds only if they contain electron-withdrawing substituents. Rate constants of the ET reactions of CO₂^{•−} are sufficiently below the diffusion-controlled range where correlations between rate constants and reduction potentials can be made.

3.1.4 Radical Reactions Involving Primary Radicals from Water Radiolysis

The Hydroxyl Radical

The electrophilic ($\rho = -0.41$) hydroxyl radical ([•]OH) is a very reactive radical, which reacts at close to diffusion-controlled rates.^{85,88,109} Rate constants for over 3500 reactions have been compiled, including reactions with molecules, ions, and radicals derived from inorganic and organic solutes.^{83,110} The [•]OH radical undergoes the following types of reactions: (i) ET, (ii) hydrogen abstraction, (iii) addition to C–C, C–N, and S–O double bonds, (iv) addition to aromatic rings, and (v) addition to electron-rich functional groups.⁸⁸

In most ET reactions involving [•]OH radicals, an intermediate complex is formed in the first step, preceding the actual ET reaction:

Since the HO–H bond dissociation energy (BDE) is very high, while the BDE of the C–H and S–H bonds are much weaker, there is a considerable

driving force for H-abstraction reactions by [•]OH radicals:

Moreover, since the BDE for primary hydrogens (–CH₃) is higher than that for secondary (–CH₂–) and tertiary (–CH–) ones, a remarkable selectivity is observed:

The yields (in percentage) of H-abstraction reactions (103a and 104a) are equal to 84.3 and 85.5%, respectively. On the other hand, the yields of H-abstraction reactions (103b and 104b) are both equal to 13.3%.¹¹¹

Since the neighboring substituents can affect the rate constants of H-abstraction reactions and thus the yield of the respective radicals, a high regioselectivity was observed. The electron-donating substituents (e.g., –OR or –NR₂) favor abstraction of a hydrogen and the electron-withdrawing groups

Scheme 2 Reactions of $\cdot\text{OH}$ radicals with 1,4-cyclohexadiene.

(e.g., $>\text{C}=\text{O}$) decrease the rate of H-abstraction. Combination of electron donation and electron withdrawal favors additionally H-abstraction.¹¹² This effect was observed in the series of amino acid anhydrides where H-abstraction by $\cdot\text{OH}$ radicals occurs at the peptide carbon.¹¹³

Addition of $\cdot\text{OH}$ radicals to C–C double bonds is very fast and occurs close to diffusion-controlled rates (e.g., for ethylene $k_{105} = 4.4 \times 10^9 \text{ dm}^3 \text{ mol}^{-1} \text{ s}^{-1}$):

For molecules in which both addition to C–C double bonds and H-abstraction reactions are possible, addition will be the generally preferred route, even for molecules having weakly bound hydrogens, such as four pentadienyl hydrogens in 1,3- and 1,4-cyclohexadienes. For instance, in 1,4-cyclohexadiene, addition to C–C double bonds occurs to an extent of 75% (Scheme 2, reaction (106a)), while H-abstraction yielding allylic radicals (**1**) occurs to an extent of only 25% (Scheme 2, reaction (106b)).¹¹⁴

Even more pronounced is the situation in the case of thymine (Scheme 3), where $\cdot\text{OH}$ addition to the C(5)–C(6) double bond is much preferred (90%) (107a and 107b) over an abstraction of allylic hydrogens at the C(5) methyl group (10%) (107c).^{5,88,115–117}

Addition of $\cdot\text{OH}$ radicals to C–N double bonds occurs in purines (guanine and adenine) (Scheme 4, reactions (108a) and (108b)). The C(8)–OH adducts (**2** and **3**) have reducing properties and their yields have been determined at 17 and 37% in guanine and adenine, respectively.^{5,88,117}

Addition of $\cdot\text{OH}$ radicals to S–O double bonds has been observed in sulfoxides (109a). The resulting

Scheme 3 Reactions of $\cdot\text{OH}$ radicals with thymine.

Scheme 4 Reactions of $\cdot\text{OH}$ radicals with purines.

Scheme 5 Reactions of $\cdot\text{OH}$ radicals with dimethylsulfoxide.

radical **4** undergoes a very rapid β -fragmentation (109b) to give the carbon-centered radical as shown in Scheme 5.¹¹⁸

Addition of $\cdot\text{OH}$ radicals to aromatic rings is probably in equilibrium with a short-lived π -complex **5** (110a) prior to transform in a

Scheme 6 Addition of $\cdot\text{OH}$ radicals to benzene.

σ -complex **6** (110b), where the OH group bounds tightly to the C-atoms (Scheme 6).¹¹⁹ A high regioselectivity is observed in these reactions: electron-donating substituents direct $\cdot\text{OH}$ radicals into the *ortho*- and *para*-positions, while electron-withdrawing substituents mostly into *meta*-position.^{120–127}

Addition of $\cdot\text{OH}$ radicals to electron-rich functional groups has been observed in disulfides **7** (111)^{109, 128–134} and sulfides **8** (112)^{109, 130–135} as shown in Scheme 7. The $\cdot\text{OH}$ adduct **9** undergoes fragmentation (113a and b) and dissociation (114). Various radical and molecular products are formed, including radicals **10** and **11** and radical cations **12**. The $\cdot\text{OH}$ adduct **13** (hydroxysulfuranyl radicals) undergoes dissociation (115a) or proton-catalyzed hydroxide ion (OH^-) elimination (115b) resulting in the formation of radical cations **14**.^{135–139} These radical cations can be stabilized by 2c–3e bonding with other heteroatoms (e.g., S, N, and O) present in sulfide molecules or undergo deprotonation at neighboring carbon atoms forming α -(alkylthio)alkyl radicals.^{134, 138–156}

The Hydrogen Atom

Radical reactions of $\cdot\text{H}$ atoms are very similar to those involving $\cdot\text{OH}$ radicals.^{77,85,86,88,109,157} Rate

constants for their reactions have been also compiled including reactions with molecules, ions, and radicals derived from inorganic and organic solutes.^{83,158}

The $\cdot\text{H}$ atoms undergo the following types of reactions⁸⁸: (i) ET, (ii) hydrogen abstraction, (iii) addition to C–C double bonds, (iv) addition to aromatic rings, (v) addition to electron-rich functional groups, and (vi) homolytic substitution.

In ET reactions, $\cdot\text{H}$ atoms are capable of reducing transition metal ions (116) and inorganic anions (117)^{159,160}:

$\cdot\text{H}$ atoms also undergo H-abstraction reactions, however, with much lower rate constants than $\cdot\text{OH}$ radicals. This is particularly reflected in a substantially lower rate constant of $\cdot\text{H}$ atoms with 2-methyl-2-propanol (118) (*vide* reaction with $\cdot\text{OH}$ (82))⁸³:

$$k_{118} = (1.7 - 11.5) \times 10^5 \text{ dm}^3 \text{ mol}^{-1} \text{ s}^{-1} \ll k_{82} = 6.0 \times 10^8 \text{ dm}^3 \text{ mol}^{-1} \text{ s}^{-1}.$$

H/D isotope effects are better pronounced in H-abstraction reactions as was seen in reaction of $\cdot\text{H}$ atoms with 2-propanol and 2-propanol- d_2 ,

Scheme 7 Addition of $\cdot\text{OH}$ radicals to disulfides and sulfides and consecutive reactions.

Scheme 8 Addition of $\cdot\text{H}$ atoms to benzene.

respectively:

The ratio $k_{\text{H}}/k_{\text{D}} = 7.5$ was measured for $\cdot\text{H}$ atoms in comparison with the $k_{\text{H}}/k_{\text{D}} = 1.5$ for $\cdot\text{OH}$ radicals.¹⁶¹

Addition of $\cdot\text{H}$ atoms to C–C double bonds is very fast and occurs close to diffusion-controlled rates (e.g., for ethylene $k_{120} = 3.0 \times 10^9 \text{ dm}^3 \text{ mol}^{-1} \text{ s}^{-1}$ ^{83,158}).

Owing to their pronounced electrophilicity ($\rho = -0.45$), $\cdot\text{H}$ atoms show a high regioselectivity in addition reactions.¹⁵⁷ If there is a competition between addition and H-abstraction, the former reaction is always preferred.⁸⁸

Addition of $\cdot\text{H}$ atoms to aromatic rings (Scheme 8, reaction (121)) leads to a σ -complex **15**, the H-atom bounds tightly to the C-atoms.

With trithianes containing three thioether groups **16** (Scheme 9), $\cdot\text{H}$ atoms react by addition to the sulfur atom (122).¹⁶² The resulting adducts **17** have not been detected because they decompose very rapidly by the ring opening followed either by α - or β -scissions (123a), further intramolecular sulfur–sulfur coupling (constituting a ring contraction) (123b), and further stabilization of the S $\cdot$ S bond thus formed by protonation (123c).

Scheme 9 Addition of $\cdot\text{H}$ atoms to trithianes and consecutive reactions.

$\cdot\text{H}$ atoms can also undergo bimolecular homolytic substitution ($\text{S}_{\text{H}}2$) with α (alkylthio) carbonyl compounds (reactions 124a and 124b).^{163,164}

The respective acetamide- and acetone-derived radicals were identified by time-resolved electron spin resonance. The above-mentioned reaction is driven by the strong S–H bond formation, while only breaking a relatively weak C–S bond, which was supported by density functional theory calculations.

Hydrated Electrons

The hydrated electron is the most powerful reductant and therefore similar to $\cdot\text{H}$ atom is capable of reducing metal ions (125) and inorganic anions (126).^{80,81,86,89,165}

Hydrated electrons react with many compounds by a dissociative electron attachment. Some selected examples of such reactions are presented:

where X=Cl, Br, and I.

Hydrated electrons react with a large number of compounds containing carbonyl, nitro, and cyano groups and with high electron affinity at diffusion-controlled rates by forming the corresponding radical anions **18–20** (Scheme 10, reactions (131)–(133)).^{83,166,167}

Hydrated electrons do not react with benzene with an appreciable rate ($k \sim 10^7 \text{ dm}^3 \text{ mol}^{-1} \text{ s}^{-1}$),¹⁶⁸ however, with benzene-containing electron-withdrawing substituents ($-\text{NO}_2$ **21**, $-\text{CN}$ **22**), the rate constants are at diffusion-controlled limit (Scheme 10, reactions (134a) and (135a)). The resulting radical anions **21**^{•−} and **22**^{•−} undergo a very rapid protonation by water, yielding the same species as expected for the reaction with $\cdot\text{H}$ atoms **23** and **24** (Scheme 10, reactions (134b) and (135b)).

Radical reactions involving primary radicals from water radiolysis have been successfully applied for generation, identification, and spectral and kinetic characterization of a large variety of radicals and radical ions in amino acids (see **Radical-Based Damage of Sulfur-Containing Amino Acid Residues**),^{5,85,106,108,154,156} peptides,^{85,108,154,156} proteins,^{108,169} nucleobases, nucleosides, nucleotides, poly-nucleotides, and DNA (see **Oxidatively Generated Nucleobase Modifications in Isolated and Cellular DNA**).^{5,88,117,170,171}

3.1.5 Radical Reactions Involving Selective Secondary Radicals from Water Radiolysis

Selective secondary inorganic radicals (Section 3.1.3) are efficient one-electron oxidizing and/or reducing agents.^{86,88} They can be used for a generation of a particular radical for study and they

Scheme 10 Reactions of hydrated electrons with aliphatic and aromatic compounds containing carbonyl, nitro, and cyano groups.

usually react without formation of intermediate adducts (such as $\cdot\text{OH}$ or $\cdot\text{H}$ adducts). For instance, the azide radical ($\cdot\text{N}_3$) was found to oxidize aromatic systems such as aniline and phenoxide ions and their derivatives at a rate constant of $(3\text{--}5) \times 10^9 \text{ dm}^3 \text{ mol}^{-1} \text{ s}^{-1}$ primarily via ET, whereas benzene, toluene, and anisole are not observably oxidized by N_3 .¹⁷² Since the majority of the above radicals are selective one-electron oxidants, they have been used in biological systems such as peptides or proteins to generate radical site primarily at aromatic and sulfur-containing amino acid side chains.^{5,85,107,108,169} The azide radical ($\cdot\text{N}_3$) shows great selectivity for tryptophan (Trp) residues.^{173–175} Similar selectivity was also shown by dichloride radical anions ($\text{Cl}_2^{\cdot-}$) and carbonate radical anion ($\text{CO}_3^{\cdot-}$). The Trp residue, the cysteine residue in the form of an anion (Cys^-), and the methionine residue in the form of monoanion (Met^-) are the preferential sites for dithiocyanate radical anion ($(\text{SCN})_2^{\cdot-}$). Dibromide radical anion ($\text{Br}_2^{\cdot-}$) reacts rapidly with

Trp, Cys, and Met residues and Cys^{•-} and tyrosine residues in the form of an anion (Tyr^{•-}).⁸⁵ These radicals were particularly useful for studying redox changes in amino acids, peptides, and proteins that were coupled very often with intramolecular LRET processes.^{85,107,173,175–179}

Intramolecular LRET reactions involving radicals located on the side chains of aromatic (Trp and Tyr), sulfur (Met and Cys), and His residues proceed on ground-state potential energy surfaces, making pulse radiolysis an effective and unique tool for these studies (see **Electron Transfer in Peptides and Proteins**). The advantage of pulse radiolysis is that using either an oxidizing or a reducing radical can generate the donor–acceptor complex.¹⁷⁸ The typical LRET pulse radiolysis experiments begin with the rapid selective oxidation or reduction of one redox site on a peptide or protein molecule, which is followed by the intramolecular LRET. Pulse radiolysis of simple model synthetic and natural peptides and native and mutant proteins have induced the following radical transformations: Trp/N[•] → Tyr/O[•] (136a and 136b),^{176,180–203} Met/S[•]:Br → TyrO[•] (137a and 137b),^{175,191,204–207} Met/S[•]:Br → Trp/N[•] (138a and 138b),^{175,191,205} CysS[•] ⇌ TyrO[•] (139a and 139b),^{175,189,206} His/N^{•+} → TyrO[•] (140a and 140b),²⁰⁸ and [CysS-SCys]^{•-} → Cu⁺ (141a and 141b)^{179,209–216};

where X = glycine (Gly) or proline (Pro) residues, $n = 0–5$, in synthetic peptides or the respective oligopeptide backbone separating Trp and Tyr residues in native peptides and proteins;

where X = proline (Pro) residues, $n = 0–4$, in synthetic peptides or the respective oligopeptide backbone, separating Met and Tyr residues in native

peptides and proteins;

where X is the respective oligopeptide backbone separating CysS-SCys and Cu²⁺ cation in native and mutant proteins (see **Electron Transfer in Peptides and Proteins**).

Biologically relevant thiyl radicals (RS[•]) have been considered for a long time as rather unreactive species. They are formed as a result of hydrogen abstraction from thiols (RSH) by primary radicals from water radiolysis: [•]OH (102) and [•]H (142), and by a dissociative attachment of hydrated electron (e_{aq}⁻) to disulfides (RSSR) (143)^{130–134}:

More recently, several reactions of RS[•] induced radiolytically have been characterized and kinetically described: H-atom abstraction from the αC–H bonds,²¹⁷ from amino acid side chain C–H bonds²¹⁸ in model peptides, and from bisallylic methylene groups in polyunsaturated fatty acid (PUFA),²¹⁹ intramolecular addition to aromatic rings,²²⁰ reversible intramolecular hydrogen transfer in peptides,^{221,222} addition to the C5–C6 double bond in pyrimidines,²²³ and catalyzed

cis/trans isomerization of lipid double bonds in mono-²²⁴ and polyunsaturated fatty acids (see **Lipid Isomerization**).^{225–230} All these reactions have been recently reviewed.¹⁵⁶

3.2 Radiolysis of Organic Solvents

The advantage of organic solvents over water is the broad range of solvent polarities available. Therefore, compounds that are insoluble in water can be studied in a suitable solvent or mixture of solvents. Moreover, depending on the solvent used, radiolysis offers a convenient method of generation of radical ions and excited states or preferentially one of them. Therefore, one may, by choice of a solvent, and in addition, of a saturating gas, exercise some control over the nature of the ionic species and excited states formed in the irradiated solvents and thus selectively generate radical ions and/or excited states derived from the solutes. There is a large variety of organic solvents that have been used for inducing radical reactions by means of high-energy radiation.²³¹ Owing to space limitations, only selective and most popular solvents are given in the following sections.

3.2.1 Radiolysis of Alcohols

Radiolysis of neat alcohols leads to the formation of the alcohol positive ions and solvated electrons (144).^{232–236} In protic polar solvents such as methanol and 2-propanol, radical anions of a solute are formed through the attachment of solvated electron to the solute molecules (145). Solute radical cations, however, are not formed since the alcohol-derived radical cations disappear rapidly producing ketyl and alkoxy radicals according to reactions depicted in (146 and 147), respectively:

Reductive ketyl radicals formed in reaction (146) can also generate radical anions of a solute according to the following reaction:

In order to study the reduction reactions of ketyl radicals without a contribution of e_{solv}^- , the alcohol solution is saturated with nitrous oxide (N_2O). Solvated electrons are rapidly scavenged by N_2O generating oxide radical ions ($\text{O}^{\bullet-}$) (149), which subsequently react with alcohol molecules forming ketyl radicals (150):

Since in alcohols mainly reductive radicals are formed, solvated electrons and ketyl radicals (144 and 146), these solvents have been used to induce selectively the one-electron reduction of solute molecules.^{237–244}

A few systems can be presented here to illustrate the generation of solute radical anions via reactions of solvated electrons and ketyl radicals with solute molecules and subsequent reactions of radical anions in alcohol solutions.

Radical anions **25** derived from (i) retinyl polyenes derivatives^{245–247} (retinal, retinol, retinol acetate retinoic acid, methyl retinoate, and *n* butylamine Schiff base of retinal) (Scheme 11, reaction (151)), (ii) retinal homologues^{245,247,248} (β -cyclocitral, β -ionone, C_{17} , C_{22} , C_{24} , and C_{30} aldehydes), and (iii) carotenes (septapreno- β -carotene, all-*trans*- β -carotene, 15,15'-*cis*- β -carotene, and all-*trans*-lycopene),^{245,249,250} astaxanthin, and canthaxanthin^{250,251} have been generated and studied in methanol and 2-propanol.

Radical anions derived from naphthalene ($\text{Nph}^{\bullet-}$), phenanthrene ($\text{Pha}^{\bullet-}$), biphenyl ($\text{Bph}^{\bullet-}$), anthracene ($\text{Anh}^{\bullet-}$), *p*-, *o*-, *m*-terphenyls (*t*- $\text{Phe}^{\bullet-}$) undergo protonation by alcohol molecules. The rate constants for reaction (153) depend on the

Scheme 11 Formation of radical anions derived from retinyl polyenes and their subsequent protonation.

properties of alcohols (acidity of the hydroxyl proton)²⁵² and the nature of the aromatic radical anion²⁵³:

Radical anions derived from retinal, retinoic acid, methyl retinoate **25**, and retinal homologues undergo protonation by alcohol molecules (Scheme 11, reaction (152)).²⁵⁴ The rate constants for protonation of radical anions in alcohols decrease on increasing the polyene chain length.²⁴⁷

Fast protonation of radical anions derived from azobenzene^{255,256} and 4-(diethylamino)-azobenzene²⁵⁶ has been observed in irradiated methanol and 2-propanol. Moreover, both ketyl radicals undergo a very fast addition with 4-(diethylamino)azobenzene²⁵⁶:

Radical anions derived from fullerenes (C_{60} , C_{70} , C_{76} , C_{78} , and C_{84}) have been generated (155 and 156) and their spectral and kinetic properties

have been characterized in 2-propanol (see **Radical Chemistry on Fullerenes**)^{257–262}:

The reduction reactions of ketyl radicals derived from 2-propanol with fullerenes (C_{60} , C_{70} , C_{76} , C_{78} , and C_{84}) (156), without a contribution of e_{solv}^- (155), have been studied in a toluene/2-propanol/acetone (8 : 1 : 1 v/v) solvent mixture.^{259–262} The $(\text{CH}_3)_2\text{C}^{\bullet}\text{-OH}$ radicals were formed in a reaction depicted in (146) and by a sequence of the following reactions: solvated electron capture by acetone followed by subsequent protonation of ketyl radical anions (157):

Alkyl radical (•CH_3) addition reaction to C_{60} has been studied in 2-propanol containing methyl iodide (CH_3I) as an electron scavenger^{257,258}:

The β -hydroxy alkyl radical ($\cdot\text{CH}_2\text{C}(\text{CH}_3)_2\text{OH}$) addition reaction to C_{60} and C_{70} has been studied in N_2O saturated 2-methyl-2-propanol (*tert*-butanol) solutions.^{259,260} The $\cdot\text{CH}_2\text{C}(\text{CH}_3)_2\text{OH}$ radical is formed in reaction (160) analogous to reaction depicted in (150):

Since $\cdot\text{CH}_2\text{C}(\text{CH}_3)_2\text{OH}$ radicals are practically redox inert, they form only adduct radicals:

Spectral parameters of radicals derived from fullerenes and absolute rate constants for reactions depicted in (155, 156, 159, and 161) have been reported.^{257–262} Radical chemistry of fullerenes has been addressed in a more detailed manner (see **Radical Chemistry on Fullerenes**).

ET reactions from radical anions of biphenyl, anthracene, and pyrene ($\text{Ar}^{\cdot-}$) to styrene (St) and *para*-substituted styrenes (*p*-X-St; X = OCH_3 , CH_3 , and Cl) have been induced in 2-propanol.²⁶³ The respective radical anions ($\text{Ar}^{\cdot-}$) formed in reactions (145 and 148) subsequently react with styrene and substituted styrenes (St) (162):

The rate constants for reactions depicted in (162) are in the range 10^6 – $10^7 \text{ dm}^3 \text{ mol}^{-1} \text{ s}^{-1}$.

3.2.2 Radiolysis of Tetrahydrofuran

Tetrahydrofuran (THF) is another example of the solvent in which selective generation of radical anions can be achieved. Pulse irradiation of a neat THF leads to formation of the THF radical cations and solvated electrons (163) and triplet states

formed by solvent radical ion recombination (164). The yield of solvated electrons in THF was found ($G \sim 0.53$) as the average of reported values. Low yields for $^3(\text{C}_4\text{H}_8\text{O})^*$ were measured. The yield of radical cations have not been measured since solvent radical cations ($(\text{C}_4\text{H}_8\text{O})^{+\cdot}$) decompose very fastly to solvated protons and radicals (165):

In this solvent, similar to alcohols (Section 3.2.1), only radical anions of solute molecules are formed:

The formation of solute radical anions or radicals in THF has been reported by many workers using a variety of solutes: organomercury compounds,^{264–266} *n*-butyl bromide and *n*-butyl iodide,²⁶⁷ biphenyl,²⁶⁷ naphthalene,²⁶⁷ retinal, and several retinal homologues.²⁴⁷

ET reactions from radical anions of biphenyl ($\text{Bph}^{\cdot-}$) and naphthalene ($\text{Nph}^{\cdot-}$) radical anions to *n*-butyl bromide (*n*-BuBr) and *n*-butyl iodide (*n*-BuI),²⁶⁸ and of biphenyl ($\text{Bph}^{\cdot-}$), anthracene ($\text{Anh}^{\cdot-}$), and pyrene ($\text{Py}^{\cdot-}$) to styrene (St) and *para*-substituted styrenes (*p*-X-St; X = OCH_3 , CH_3 , and Cl),²⁶³ have also been induced in THF. The respective radical anions formed via reaction (166) subsequently react with *n*-butyl bromide and iodide (167) and styrene and substituted styrenes (St) (162):

Recently, several interesting studies have been performed using radiolysis of THF for inducing radical reactions in large organic molecules. The formation of radical anions in parent and terthiophene end-capped poly(arylene-ethynylene) polymers **26** (Scheme 12) have been accomplished in an effort to characterize the spectra and dynamics of the radical anions of the polymers.²⁶⁹

One electron reduction of an “extended viologen” *p*-phenylene-bis-4,4'-(1-aryl-2,6-diphenylpyridinium) dication (EV^{2+}) **27** (Scheme 12)

Scheme 12 Structural formulas of terthiophene end-capped poly(arylene-ethynylene) polymers and extended viologen *p*-phenylene-bis-4,4'-(1-aryl-2,6-diphenyl-pyridinium) dication.

has been induced in THF, showing that e_{solv}^- reacts very rapidly with EV^{2+} ($k = (4.2 \pm 1.5) \times 10^{11} \text{ dm}^3 \text{ mol}^{-1} \text{ s}^{-1}$) and the monomeric radical cation produced has a fully delocalized electronic structure.²⁷⁰

ET reactions from the radical anion of poly-2,7-(9,9-dihexyfluorene) ($\text{pF}^{\bullet-}$) to benzophenone (BzPh), nitrobenzene (NBz), and pyrene (Py) have also been induced in THF.²⁷¹ The radical anion ($\text{pF}^{\bullet-}$) formed via reaction (166) subsequently reacts with BzPh, NBz, and Py (168–170). Reaction with pyrene does not lead to completion but to an equilibrium (170):

The formation of radical anions in polyfluorenes having anthraquinone (AQ) or naphthylimide (NI) end caps that trap electrons have enabled studies on ET along the chains of conjugated polymers.²⁷² An electron attachment to a polyfluorene chain is followed by a fast ET to and trapping by end cap

(AQ/NI):

The attachment rate constants to fluorene oligomers (oF) and fluorene polymers (pF) have been determined. It was found that in going from oF₁ to pF₁₃₃, k increases by a factor of 16, which is much smaller than the 133-fold increase in length.²⁷³

3.2.3 Radiolysis of Acetonitrile

Acetonitrile is known for pulse radiolytic generation of radical cation as well as radical anion precursors.^{274–277} Pulse irradiation of a neat acetonitrile leads to the formation of the acetonitrile positive ions and electrons/negative ions (172 and 173) and triplet states formed by solvent radical ion recombination (174 and 175). Low yields of G for the oxidizing species (~ 0.2)²⁷⁷ and for the triplets (~ 0.3) were measured.²⁷⁵ On the other hand, the

yield of reducing species was found in the range of $G = 1.03\text{--}1.55$ ²⁷⁶:

In this solvent saturated with Ar, both radical ions can be formed (176–178), while in O₂-saturated solution only radical cations of a solute are formed (178) (ionization potential of CH₃CN is ≈ 12 eV). Solute radical anions are not formed since their precursors, solvated electrons, and/or solvent radical anions are scavenged by O₂ (179):

Oxygen also serves as a strong quencher for triplets of solutes and solvents.

Radical ions derived from phenol,²⁷⁷ benzhydrol,²⁷⁷ phenothiazine,²⁷⁷ BzPh,^{276,277} biphenyl,^{276,277} naphthalene,²⁷⁵ anthracene,²⁷⁵ pyrene, 4-nitro-benzyl compounds,²⁷⁸ *N*-methylacetamide,²⁷⁹ tri-*p*-tolylamine,²⁷⁷ triphenylamine,²⁷⁷ retinal,²⁴⁸ 7-aminocoumarin dyes,²⁸⁰ and oxoisoaporphines derivatives^{281,282} have been generated according to reactions depicted in (176)–(177) and (178), respectively, and characterized spectrally.

Reactions of $\cdot\text{CF}_3$ radicals with pyrene, phenanthrene, and crotonic acid (CA) (180) have been induced in CF₃Br-saturated acetonitrile.²⁸³ These reactions undergo $\cdot\text{CF}_3$ addition to form pyrene/phenanthrene rings and a double bond in CA:

$\cdot\text{CF}_3$ radicals are formed in the following reactions:

3.2.4 Radiolysis of Acetone

Radiolysis of acetone leads to the relatively long-lived radical ions (183 and 184) and triplet states (formed via geminate recombination (185)).^{284,285} The free ions and triplet yields were measured to be 0.75 and 1.0, respectively.²⁸⁶ Radical cations and anions of acetone are involved in charge transfer to a solute, which leads to the radical cations and radical anions of a solute, respectively (186 and 187). On the other hand, triplets of acetone are involved in energy transfer to a solute that leads to a triplet of a solute (188):

In this solvent saturated with Ar, both radical ions and triplets can be formed according to (186–188), while in O₂ saturated solution, only radical cations of a solute are formed. The total yields of excited states ($G = 1.3 \pm 0.1$) and of free ions ($G = 1.2\text{--}1.7$) were found.

The formation of $(\text{SCN})_2^{*-}$ has been observed via the following reactions²⁸⁷:

Some selected illustrative examples of dissociative ET reactions involving tetranitromethane,²⁸⁸

Scheme 13 Tautomerism of radical cations derived from methylated uracils and thymines.

carbon tetrachloride and leucocyanide of malachite green dye (MGCN)²⁴¹ induced in irradiated acetone are depicted in the following equations (190–192):

Radical cations and anions and triplet excited states of naphthalene,^{284,287} anthracene,^{287,289} pyrene,²⁸⁴ biphenyl,²⁸⁷ *trans*-stilbene,²⁸⁷ nitromethane,²⁹⁰ retinyl polyenes derivatives (retinal, retinol, retinol acetate retinoic acid, methyl retinoate, and *n*-butylamine Schiff base of retinal),²⁹¹ and retinal homologues (β -cyclocitral, β -ionone, C₁₇, C₂₂, C₂₄, and C₃₀ aldehydes)²⁴⁷ have been generated (186–188) and studied in acetone.

Radical cations ($\text{S}^{\bullet+}$) derived from pyrene,^{284,292} naphthalene,²⁸⁴ 2,6-dimethyl-naphthalene,²⁸⁴ retinal,²⁹³ retinoic acid,²⁹³ and methyl retinoate²⁹³ were found to interact with neutral, ground-state solute molecules (S) forming dimeric radical cations (193):

The dependence of the kinetics of the decay/formation processes on solute concentration can be rationalized in terms of dimer/monomer radical cation equilibria.

Radical cations of multiple methylated uracils (U) and thymines (T) were generated in acetone (194) and acetone/*n*-butyl chloride mixtures (195) (for formation of *n*-C₄H₉Cl⁺, Section 3.2.5)²⁹⁰:

These radical cations show a transient tautomerism and exist in acetone in a lactim- and in *n*-butyl chloride in a lactam-like form (Scheme 13).²⁹⁰

3.2.5 Radiolysis of Halogenated Hydrocarbons

Radiolysis of halogenated solvents such as dichloromethane (CH₂Cl₂), 1,2-dichloroethane (ClCH₂CH₂Cl), and *n*-butyl chloride (*n*-C₄H₉Cl) generates radical cations or radicals that are very strong oxidants.^{294,295} In irradiated halogenated hydrocarbon liquids, after initial ionization process (196a–196c), the secondary electrons undergo a very fast dissociative attachment to the solvent, forming relatively unreactive free radicals and

chloride ions which do not react with the solute (197):

Thus, direct reactions of electrons with the solutes of interest are eliminated, and these halogenated hydrocarbon solvents are convenient for the selective generation of solute radical cations.

In the presence of additives (S) of lower ionization potential as the above solvents, a rapid ET takes place:

Radical cations derived from retinal and retinoic acid have been generated,²⁹¹ and their subsequent reactions with respective solutes forming dimeric radical cations have been observed in 1,2-dichloroethane.²⁹³

Radical cations derived from fullerenes (C_{60} , C_{70} , C_{76} , C_{78} , and C_{84}),^{257–262} and chlorinated fullerenes (C_{60}Cl_6 and $\text{C}_{60}\text{Cl}_{12}$),²⁹⁶ have been generated (199) and their spectral and kinetic properties have been characterized in 1,2-dichloroethane and dichloromethane (see **Radical Chemistry on Fullerenes**):

Rate constants of $\text{CH}_2\text{CH}_2\text{Cl}^{\bullet+}$ radicals additions to C_{60} and C_{70} (200) have been measured in 1,2-dichloroethane ($k_{200} = 2.2 \pm 0.5 \times 10^9 \text{ dm}^3$

Scheme 14 Cis/trans-Isomerization of radical cations derived from stilbene derivatives.

$\text{mol}^{-1} \text{ s}^{-1}$ for C_{60} ²⁵⁹ and $1.9 \times 10^9 \text{ dm}^3 \text{ mol}^{-1} \text{ s}^{-1}$ for C_{70})²⁶⁰:

Formation of dimer radical cations of $\text{C}_{60} / \text{C}_{70} / \text{C}_{76} / \text{C}_{78}$ fullerenes according to reaction depicted in (201) have been studied in 1,2-dichloroethane and dichloromethane:

The bimolecular rate constants k_{201} were 6.0×10^9 , 6.0×10^9 , 7.9×10^8 , and $9.8 \times 10^9 \text{ dm}^3 \text{ mol}^{-1} \text{ s}^{-1}$ for C_{60} , C_{70} , C_{76} , and C_{78} , respectively.^{259,260,262}

The ET reactions from the ground state of C_{76} and C_{78} to radical cations of various arenes (202) have evidenced the Marcus inverted region.^{297–299} The formation of the arene radical cations has been achieved by reaction of $\text{CH}_2\text{Cl}_2^{\bullet+}$ with the respective arenes, analogous to reaction depicted in (199):

Generation of radical cations of stilbene derivatives **28** and **29** and their further reactions, cis to trans isomerization (Scheme 14), oxidation, and dimerization, have been induced and studied in dichloroethane and *n*-butyl chloride.³⁰⁰ Remarkable enhancement of isomerization and oxidation

Scheme 15 Generation of intramolecular dimer radical cations of cyclophanes.

of stilbene radical cations was observed resulting from charge-spin separation induced by $-\text{OCH}_3$ groups.³⁰¹

The radical cations of oligothiophenes (nT), with number of rings $n = 1-6$, have been generated in dichloromethane.³⁰² The electronic transitions for radical cations move to lower energy as the number of thiophene rings increases. This is interpreted as a result of an extended delocalization of π -system along the chain.³⁰²

Recently, generation of highly stabilized intramolecular dimer radical cations of cyclophanes **30**, containing π -stacked multi-benzene rings connected by propyl chains, has been achieved in 1,2 dichloroethane (Scheme 15). It was revealed that efficient charge delocalization over the cyclophanes occurs and the stabilization energy depends on the distance between the two benzene rings and the number of benzene rings.³⁰³⁻³⁰⁵

Using $n\text{-C}_4\text{H}_9\text{Cl}^{\bullet+}$ as a very efficient electron acceptor toward a large variety of organic donor molecules (198), a phenomenon called *free electron transfer* (FET) has been thoroughly studied in some substituted aromatic compounds: phenol³⁰⁶⁻³⁰⁸ and substituted phenols,³⁰⁶⁻³¹¹ thiophenol^{306,308,312} and substituted thiophenols,^{308,310,312} seleno-phenol,^{308,313} aromatic amines,^{314,315} sulfides³¹⁶ and silanes,^{317,318} naphthols,^{312,319} hydroxybiphenyls,³¹⁹ trityl-containing compounds,³²⁰ and amino-, thio-, and hydroxynaphthalenes.³²¹ All these compounds constitute a group of molecules that fulfils the structural conditions necessary for FET, that is, they exhibit a low-energy barrier to rotation about the $\text{C}_{\text{sp}^2}\text{-X}$ bond. A parallel formation of two different and distinguishable FET products was observed, the expected metastable solute radical cations ($\text{X}^{\bullet+}$)

Scheme 16 Reaction sequence in free electron transfer involving phenols.

31 and the corresponding solute-derived radicals ($\text{X}^{\bullet}$) **32** (Scheme 16).

Two excellent and comprehensive reviews that present and discuss these problems in a more detailed manner have been published recently.^{322,323}

3.2.6 Radiolysis of Hydrocarbons

Liquid hydrocarbons such as alkanes, alkenes, and cycloalkanes have been used for generation of radiation in radical ions. *n*-Hexane and cyclohexane

were the most commonly used solvents.^{36, 324–329} Radiolysis of these hydrocarbons (RH) produces excited states (RH*) and electron-hole pairs (e[−], RH^{•+}):

Because of the low dielectric constant ($\epsilon \sim 2$), the bulk of the ion recombination is geminate yielding energetic, excited solvent molecules:

Few of these electrons, however, can escape ion recombination and in the presence of solute, they can react forming solute radical anions (S^{•−}):

The solvent “hole” produced is characterized by a high mobility and they can undergo several ion-molecule reactions including charge (206) and proton (207) transfer reactions with solutes:

The rate constants of charge transfer processes are very high, that is, $(1-5) \times 10^{12}$ and $(10^{10}-10^{11}) \text{ mol}^{-1} \text{ dm}^3 \text{ s}^{-1}$ for reactions depicted in (206 and 207), respectively. These rates are higher in cyclohexane than in other *n*-alkanes.^{327–329}

These reactions and their radical-ion products were studied using nano- and picosecond pulse radiolysis.^{330–333}

Radical cations derived from tetraphenylethylene³³⁴ have been generated in cyclohexane solutions. The formation of intra- and intermolecular radical cation complexes during oxidation of organic di-, tri-, and tetrathia compounds (1,4- and 1,3-dithiacyclohexane, 1,3,5-trithiacyclohexane, 1,4,7,10-tetrathiacyclododecane, 1,5,8,12-tetrathiacyclotetradecane, 4-methyl-3,5-dithiaheptane in neohexane and 3-methylpentane,³³⁵ and radicals with the intermolecular 2c–3e bond between sulfur and iodide in 1-halo-2-(methylthio)ethanes³³⁶ has been observed.

Radical cations derived from (i) retinal homologues (β -ionone²⁴⁵ and β -ionylidene acetaldehyde),²⁴⁵ (ii) retinyl derivatives (retinal^{245,291} and

retinoic acid²⁹¹), and (iii) carotenes (β -apo-8'-carotenal,²⁴⁵ all-*trans*- β -carotene,²⁴⁹ 15,15'-*cis*- β -carotene,²⁴⁹ and all-*trans*-lycopene),²⁴⁹ 7,7'-dihydro- β -carotene,²⁵⁰ septapreno- β -carotene,²⁵⁰ decapreno- β -carotene,²⁵⁰ dodecapreno- β -carotene,²⁵⁰ and canthaxanthin²⁵⁰ have been generated in *n*-hexane and cyclohexane in a charge transfer process.

3.3 Radiolysis of Ionic Liquids

Ionic liquids (ILs) are defined as *molten salts* with melting points below 100°C. These salts are a combination of organic and inorganic ions. Owing to their unique properties, ILs are attractive media for generation of radicals (see **Free Radical Chemistry in Room-Temperature Ionic Liquids**).^{337,338}

For water and organic solvents, the knowledge about the nature of primary reactive species and the approaches to convert them into specific radical intermediates is rather broad (*vide supra*). A similar knowledge has to be assembled for IL. Therefore, understanding the chemistry of IL under high-energy radiation is crucial for designing IL composition to induce specific radical reactions.

The two major processes that occur in irradiated ILs are excitation (208) and ionization (209) of IL molecules^{339–343}:

The ejected electrons start to lose their excess kinetic energy and become “thermalized” (210). These electrons are not equilibrated with the surrounding molecules and therefore they are called dry or presolvated. As the solvation process proceeds, the electrons become more and more localized and solvated, eventually.

They can also undergo recombination with the “holes” to produce a ground or excited states of the IL anions or cations:

In the presence of electron scavengers, both types of electrons can form radical anions:

where S designates different types of electron scavengers: those reacting either with presolvated or solvated electrons and those reacting with both of them.

“Holes” resulting from ionization (209) can undergo recombination with electrons (211), fragmentation into fragments of any type, including radicals (213) or in the presence of “hole” scavengers form radical cations (214):

Different classes of IL on irradiation can produce different reactive intermediates, which is often advantageous. Therefore, IL can provide a new environment to induce by radiation and to test radical reactions including charge transfer processes.

Most of the radiation-induced radical intermediates have been studied in IL composed of imidazolium (BMIM⁺),^{341,344–350} quaternary ammonium (R₄N⁺),^{283,341,347,351–360} pyrrolidinium,^{341,347,348,354} pyridinium (Py),^{347,348,351,354} phosphonium cations,^{341,348} and bis(trifluoromethylsulfonyl)imide,^{283,341,347,351–360} dicyanamide,³⁴¹ bis(oxalato)-borate,^{341,348} tetrafluoroborate (BF₄[−]),^{351,354,359} hexafluorophosphate (PF₆[−]),^{346,349,351} chloride (Cl[−]),³⁵⁰ bromide (Br[−]),³⁵⁰ thiocyanate (SCN[−]),³⁵⁰ and azide (N₃[−]) anions.³⁵⁰

Since the issue of free radical chemistry in ILs has already been addressed (see **Free Radical Chemistry in Room-Temperature Ionic Liquids**), here only a few typical examples of radiation-induced radical reactions in various ILs are presented.

The radical cations from 1-methyl-1,4-dihydronicotinamide,³⁴⁴ chlorpromazine (215–217)), and *N,N,N,N'*-tetramethyl-*p*-phenylenediamine (TMPD) (215 and 218),³⁴⁵ and the radical cations and anions from benzoquinone, duroquinone (DQ), methyl viologen, chlorpromazine (CIPz), 6-hydroxy-2,5,7,8-tetramethylchroman-2-carboxylic acid (Trolox), and thiophene and its substituted derivatives were generated in the IL 1-butyl-3-methyl-imidazolium (BMI⁺) with

hexafluorophosphate (PF₆[−]) and tetrafluoroborate anions (BF₄[−])^{345,349}:

Dihalide (Cl₂^{•−} and Br₂^{•−}) and pseudo-halides ((SCN)₂^{•−} and N₆^{•−}) radical anions have been selectively generated in IL containing 1-butyl-3-methyl-imidazolium (BMI⁺) cation with Cl[−], Br[−], SCN[−], and N₃[−] anions (215, 219, and 220)³⁵⁰:

The reactions of the reductive butylpyridinyl radicals (BuPy[•]) with DQ, methyl viologen (MV²⁺), *p*-nitrobenzoic acid, and *p*-nitroacetophenone (221–223) were induced and studied in the ILs *N*-butylpyridinium tetrafluoroborate (BuPyBF₄) and *N*-butyl-4-methylpyridinium hexafluorophosphate (BuPyMePF₆). Solvated electrons cannot reduce solutes in these ILs since they are rapidly scavenged by the pyridinium cations (222)^{351,354}:

(BuPy)²⁺/BuPyMe²⁺ and BF₄[•]/PF₆[•] act as oxidants or undergo fragmentation.

The addition reactions of trifluoromethyl radicals ($\text{CF}_3^\bullet$) to pyrene (Pyr), phenanthrene (Phen), and CA (224–228) were induced and studied in IL methyltributylammonium bis(trifluoromethylsulfonyl)imide (R_4NNTf_2) saturated with or in acidic medium without CF_3Br .²⁸³ The solvated electrons do not react with the solvent ions (R_4N) and $(\text{CF}_3\text{SO}_2)_2\text{N}^-$ and are scavenged by CF_3Br (225):

Trifluoromethyl radicals can be also formed via fragmentation of $\text{CF}_3\text{SO}_2\text{N}^\bullet$ radicals (241) and/or from excited states formed by geminate recombination (242):

The same IL was used to induce and study (i) hydrogen abstraction reactions of $\text{CF}_3^\bullet$ radicals (229–230) and alkyl radicals (231–232) from 2-propanol and 4-mercaptobenzoic acid (229, 230, and 232)^{283,352}:

(ii) reduction of several solutes, including CCl_4 , BzPh, pyrene, quinones, and chlorophenols

by dry and/or solvated electrons,^{351,356,358–360} (iii) hydrogen atom addition reactions in acidic medium to pyrene (Pyr), phenanthrene (Phen), BzPh (233–234a), CA (233–234b), and hydrogen abstraction from 2-propanol (233 and 235),³⁵⁵

(iv) generation and reactions of dihalide radical anions (236–238) and their subsequent oxidation reactions on saturation with 1,2-dibromoethane,^{353,357}

where $\text{X} = \text{Br}$ and SCN .

4 RADIATION-INDUCED RADICAL REACTIONS IN SOLIDS

4.1 Basic Considerations

Radiolysis of solids differs from radiolysis of gases and liquids because of the higher electron density of the absorbing medium and decrease in freedom of the ionized and excited species. Since the distance traveled by energetic electrons in depositing their energy is inversely proportional to the density of the medium, the tracks are shorter and the spur radii are smaller in the solid than in the liquid. Therefore, in the solid state, the ionized and excited species will be much more closely confined and the deposited

energy will be limited to very small regions. Thus, the distribution of the species is dependent on LET. As the solids are irradiated, the primary processes of excitation and ionization take place and electronically excited molecules and atoms, radical ions, radicals, and stabilized electrons are formed. However, the close proximity of neighboring molecules in the solid favors deactivation over decomposition and thus favors prompt recombination in the parent cage. Radiation-induced radical reactions in solids have not been studied so thoroughly as in gases or liquids. This is partly justified since the dynamic, structural, and relaxation properties of a solid may play a decisive role in energy and charge transfer processes.

There are several comprehensive reviews and books, which discuss the topic of radiation generation of radical ions in solids in a detailed manner.^{2,36,361–365} Radiation-induced reactions in aqueous glasses,^{366,367} organic glasses,^{361,368} low-temperature rare gas matrices,^{364,365} involving radicals and radical ions derived from a large variety of compounds have been reviewed, previously. A special attention has been paid to radiation-induced radical reactions in amino acids, peptides, proteins, nucleobases, and DNA present in aqueous glasses and in crystalline states. The reader is referred to several excellent reviews for details,^{88,108,169,171,369–372} which cannot be covered in depth here.

This section highlights only the recently obtained examples of radiation-induced radical reactions in zeolites, a new matrix used for radiation generation of radicals and radical ions in the solid state.

4.2 Radiolysis of Zeolites

Zeolites are crystalline aluminosilicates. Their lattice consists of a network of SiO_4^- and AlO_4^- tetrahedra with Si and Al atoms at the centers and oxygen atoms in each corner.³⁷³ These rigid microporous solids can serve as excellent matrices for generating and stabilizing otherwise reactive and unstable radical cations. Radical cations in zeolites have increased lifetimes since the restricted mobility within zeolite pores limits the tendency of free radicals and radical cations to react with other reagents.^{374–376}

Energy deposited in zeolites by high-energy radiation generates “holes” (Z^+) and trapped electrons in zeolite matrix:

In the presence of adsorbate (A), “holes” (Z^+) migrate to adsorbate molecule “guests” by charge transfer:

Since the redox and the acid–base properties depend on the zeolite, one has to be aware that it is not always obvious whether the original substrate or a rearranged product is oxidized by interaction with the zeolite “hole” Z^+ .

A large variety of radical cations and radicals have been generated in zeolites.³⁷⁶ This section is restricted to the most relevant examples of generation of radical cations and radicals generated in linear and branched alkanes,^{377–380} cycloalkanes,^{380,381} strained-ring compounds,³⁸² alkenes,^{378,382–385} C_7H_8 hydrocarbons,^{380,386,387} ethynes,³⁸⁵ and polynuclear aromatics^{388–390} on radiolysis.

Generation and subsequent proton transfer, fragmentation, and deprotonation reactions of radical cations derived from linear *n*-hexane **33** and branched 2,3-dimethylbutane **34**, 2,2,3-trimethylbutane **35**, and 2,2,3,3-tetramethylbutane **36** (Scheme 17) have been observed in ZSM zeolites.^{377,379,380}

Cyclohexane³⁸⁰ and cis/trans-decaline³⁸¹ radical cations have been generated and characterized in ZSM-5 and in a number of synthetic zeolites, respectively. In the latter case, it was found that both cis/trans-decaline radical cations exist in two different electronic states.

Radical cations of 1,1,2,2-tetramethylcyclopropane (TMCP^+) **37** and hexamethylbicyclo-hexa-2,5-diene (Dewar benzene) (HMCH^+) **38** have been generated in Na–Y zeolite and characterized by ESR spectroscopy.³⁸² On the other hand, radiolysis of *trans*-2,3-dimethyl-1-oxacyclopropane resulted in the formation of a ring-opened radical species (DMOCP^+) **40** (Scheme 18) without preceding formation of a delocalized, ring-opened radical cation **39**.³⁸²

Extensive studies on radiolytically generated radical cations derived from alkenes in a number of synthetic zeolites (Na–Y, Na–X, and ZSM-5) have been performed.^{383–385,391} Radiolysis of 2,3-dimethyl-1-butene (2,3-DMB) **41**

Scheme 17 Generation of radical cations in *n*-hexane and branched methylbutanes and their subsequent reactions.

Scheme 18 Generation of radical cations in cyclic alkanes.

in various zeolites resulted in the formation of monomer radical cation (2,3-DMB^{•+}) **41**^{•+}, 2,3-DMB radical (2,3-DMB[•]), and π -dimer radical cation (2,3-DMB)₂^{•+}.³⁹¹ Interestingly, radiolysis of 3,3-dimethyl-1-butene (3,3-DMB) **42** resulted in the formation of the same radical cation (2,3-DMB^{•+}) **41**^{•+}, without preceding respective radical cation (3,3-DMB^{•+}) (Scheme 19).³⁸⁴

Isomerization of 1,4-cyclohexadiene radical cation (1,4-CHD^{•+}) **43** generated radiolytically in

ZSM-5 zeolites into the 1,3-cyclohexadiene radical cation (1,3-CHD^{•+}) **44** has been observed for cyclohexadienes (Scheme 19).

Radiolytically generated radical cations and radicals derived from several C₇H₈ hydrocarbons (norbornadiene (NB), quadricyclane (QC), bicyclohepta-2,5-diene (BCHD), and cycloheptatriene (CHT)) have been investigated in Na-ZSM-5 zeolite.³⁸⁶ Interesting transformations involving radical cations have been observed. Depending on

Scheme 19 Generation of radical cations in alkenes.

Scheme 20 Generation of radical cations in C_7H_8 hydrocarbons and their subsequent reactions.

the temperature, the NB radical cation ($NB^{\bullet+}$) **45** was found to rearrange into cyclopentadiene radical cation ($CP^{\bullet+}$) **46**, which further deprotonates giving cyclopentyl radical ($CP^{\bullet}$) **47** or converts either into BCHD radical cation ($BCHD^{\bullet+}$) **48** or the norbornadien-7-yl radical ($NB^{\bullet}$) **49** (Scheme 20). CHT radical cation ($CHT^{\bullet+}$) **50** deprotonates to heptatrienyl radical ($CHT^{\bullet}$) **51** (Scheme 20).³⁸⁰ The QC radical cation ($QC^{\bullet+}$) **52** undergoes a very fast valence isomerization leading to $NB^{\bullet+}$ **45**.^{386,387}

Radiolysis of ethyne (acetylene), adsorbed on Na-ZSM-5, resulted in formation of benzene radical cation³⁹²:

Naphthalene, anthracene, and pyrene radical cations have been generated on radiolysis of naphthalene in ZSM-5,³⁹⁰ anthracene in Y zeolites,³⁸⁸ and pyrene in silica/alumina,³⁸⁹ respectively. Methyl radicals ($\cdot\text{CH}_3$) and their complexes ($\cdot\text{CH}_3 \cdots \text{Na}^+$) with Na^+ have been generated in Na-A zeolites.³⁹³ Organosilver radicals ($\text{Ag}^{\bullet}\text{CH}_2\text{OH}$) have been generated in Ag-A/ CH_3OH zeolite.^{394,395}

5 CONCLUSIONS

Over 100 years have passed since the discovery of X-rays by Roentgen and radioactivity by Henry Becquerel, Maria Skłodowska-Curie, and Pierre Curie. These very important events were crucial for the development of radiation chemistry, which is concerned with the interaction of various types of high-energy radiation (γ - and X-radiation, charged particles) with matter. In the twentieth century and also the first decade of the twenty-first century, radiolysis has played a substantial and important role in providing the experimental approach for generation of radicals and radical ions, induction of radical reactions, and understanding their reaction mechanisms. In many cases, high-energy radiation offers a convenient and relatively easy way of induction of radical reactions in all phases (gases, liquids, and solids) that cannot be or can be performed with some limitations by chemical, electrochemical, and photolytic methods. With the recent progress in the time-resolution of pulse radiolysis and increased capabilities of analytical techniques available, high-energy radiation approach for inducing radical reactions is highly promising to complement these methods.

ACKNOWLEDGMENTS

Thermochemistry and Hydrogen Transfer Kinetics

Andreas A. Zavitsas

Department of Chemistry and Biochemistry, Long Island University, Brooklyn, NY, USA

1 INTRODUCTION

Chemical transformations appear conceptually simple. Some bonds are broken and others are made. Knowledge of the energy required to break bonds and energy released on making bonds are basic to our understanding of chemical reactivity. Sometimes, surprisingly, reactivity is controlled by the strength of a chimera bond, one that is never broken or made. In seeking an understanding of the factors that influence reactivity, one of the first issues to be addressed is the effect of molecular structure. Many of the synthetic reactions in a chemist's arsenal are ion–molecule reactions. However, examining available data of the rates of such reactions presents a major difficulty. For example, S_N2 reaction rates can be accelerated by tens of thousands of times by simply changing the solvent from ethanol to dimethyl sulfoxide and generally do not occur at all in the gas phase near ambient temperatures. Such reaction rates are not simply a function of the molecular structure of the reactants and products but are greatly affected by interactions of reactants, transition state (TS), and products with the particular solvent. In the quest of understanding chemical reactivity in terms of properties of reactants and products, a study of radical reactions is advantageous. Reactions of neutral radicals often proceed at comparable rates in the gas phase and in various nonpolar solvents, that is, with very similar pre-exponential terms and activation energies of the Arrhenius expression of the

rate constant $k = A \times \exp(-E_a/RT)$, and we have an easier task at discerning structure–reactivity relationships and patterns.¹ Significant solvent effects have been reported to occur in some special cases of radical reactions, generally reactions of radicals that form strong hydrogen bonds with the substrate and/or with H-bonding solvents or reactions of radicals with substrates that form strong hydrogen bonds with the solvent or with themselves. Typical examples are hydrogen abstractions by oxyl radicals from RO–H and by $R_2NO\cdot$ from R_2NO-H (see **Supramolecular Radical Chemistry**).^{2,3}

Understanding the factors affecting radical reactivity has led to current widespread use of radical reactions in organic synthesis. Complex natural product synthesis and a better understanding of radical reactions in biological systems have been accomplished. Excellent reviews of these aspects have appeared.^{4,5} Other articles of this encyclopedia also address synthetic applications. There is interest in radical–molecule reactions because they are also involved in the aging process, combustion, DNA repair, ozone depletion, and so on.

Knowledge of bond dissociation enthalpies (BDEs) of the bonds that are being broken and made allows an easy calculation of the thermochemistry of the reaction. The enthalpy of reaction is given by comparing the strength of the bonds being made to those being broken via an application of Hess's Law, (1), to the reaction $A-B + C-D \rightarrow A-C + B-D$. If the sum of the

strengths of the bonds made is greater than that of the bonds broken, the reaction is exothermic.

$$\Delta H_{\text{rxn}} = -\text{BDE}[\text{A}-\text{C}] - \text{BDE}[\text{B}-\text{D}] + \text{BDE}[\text{A}-\text{B}] + \text{BDE}[\text{C}-\text{D}] \quad (1)$$

For example, in halogenations of methane, $\text{H}_3\text{C}-\text{H} + \text{X}-\text{X} \rightarrow \text{H}_3\text{C}-\text{X} + \text{H}-\text{X}$, and the enthalpy of reaction is given by $\Delta H_{\text{rxn}} = -\text{BDE}[\text{H}_3\text{C}-\text{X}] - \text{BDE}[\text{H}-\text{X}] + \text{BDE}[\text{H}_3\text{C}-\text{H}] + \text{BDE}[\text{X}-\text{X}]$.

Enthalpies of reaction are easily obtained from the known gas-phase BDE at 298.15 K of each bond involved. In kilojoules per mole at 298.15 K, the enthalpy of the reaction calculated by (1) and the known BDEs for $\text{X} = \text{F}$ is -432.6 ; for $\text{X} = \text{Cl}$ it is -101.3 ; for $\text{X} = \text{Br}$ it is -26.8 ; and for $\text{X} = \text{I}$, it is 53.1 . From this simple calculation, the indication is that, if fluorination occurs, the great exothermicity might lead to a runaway reaction or explosion. Safety considerations would suggest the need for great care and high dilutions in carrying out free-radical fluorinations of hydrocarbons. Iodination is endothermic and unlikely to proceed at a reasonable rate at room temperature, but proceeds at higher temperatures. Chlorination and bromination of hydrocarbons are exothermic overall and could proceed with radical chain initiators at or near room temperature in systems purged of radical traps or O_2 , especially when weaker $\text{C}-\text{H}$ bonds are involved. Experimental studies of these reactions confirm the indications obtained from the calculated reaction enthalpies.

Another formulation of Hess's Law uses enthalpies of formation $\Delta_f H^\circ$ of reactants and products to obtain the thermochemistry of the reaction $\text{A}-\text{B} + \text{C}-\text{D} \rightarrow \text{A}-\text{C} + \text{B}-\text{D}$ by (2).

$$\Delta H_{\text{rxn}} = \Delta_f H^\circ[\text{A}-\text{C}] + \Delta_f H^\circ[\text{B}-\text{D}] - \Delta_f H^\circ[\text{A}-\text{B}] - \Delta_f H^\circ[\text{C}-\text{D}] \quad (2)$$

$\Delta_f H^\circ$ is the change in enthalpy caused by the formation of 1 mol of a substance in the standard state from the constituent elements in their most stable form in the standard state. The standard state is 1 atm of pressure at 298.15 K. The enthalpy of the most stable form of every element in its standard state is zero by definition. For example, if the reaction of 1 mol of graphite (the most stable form of solid carbon at 298.15 K and 1 atm) with oxygen at 298.15 K and 1 atm releases $-393.51 \text{ kJ mol}^{-1}$ to

form 1 mol of carbon dioxide at 298.15 K and 1 atm, then $\Delta_f H^\circ[\text{CO}_2] = -393.51 \text{ kJ mol}^{-1}$.

An example of an application of (2) is the polymerization of ethylene, modeled by $\text{CH}_3\text{C}^\bullet\text{H}_2 + \text{CH}_2 = \text{CH}_2 \rightarrow \text{CH}_3\text{CH}_2-\text{CH}_2-\text{C}^\bullet\text{H}_2$. The needed enthalpies of formation are known:

$$\Delta_f H^\circ[\text{CH}_3\text{C}^\bullet\text{H}_2] = 120.9 \text{ kJ mol}^{-1},$$

$$\Delta_f H^\circ[\text{CH}_2=\text{CH}_2] = 52.5, \text{ and}$$

$$\Delta_f H^\circ[\text{CH}_3\text{CH}_2\text{CH}_2\text{C}^\bullet\text{H}_2] = 79.1.$$

Hence, $\Delta H_{\text{rxn}} = -94.3 \text{ kJ mol}^{-1}$. The polymerization is exothermic and measures must be taken to have sufficient cooling capacity to remove this heat from the polymerization vessel. (Note: Throughout this article, the radical sign “ $\bullet$ ” immediately follows the atom bearing the odd electron. Energy units are in kilojoules per mole throughout, $4.184 \text{ kJ} = 1.000 \text{ kcal}$.)

BDEs may be obtained directly by measuring the amount of energy required to break a particular bond homolytically, generating free radicals in their ground states. One way is via spectroscopic measurements of the observed quantized energy levels of a diatomic gas such as HF up to its dissociation limit.⁶ Alternatively, one may establish the minimum light frequency ν required to bring about the dissociation of Cl_2 into two chlorine radicals, by calculating the energy by $\text{BDE}[\text{Cl}-\text{Cl}] = h\nu$, where h is the Planck constant and ν is the frequency required for bond cleavage. Kinetic measurements are also made by measuring the reaction rate constant for breaking a particular bond as a function of temperature in pyrolysis studies, usually under very low pressure conditions to avoid possible chain decompositions. The energy of activation for such homolytic bond cleavage is a good estimate of its BDE in the temperature interval measured.

In addition to kinetic measurements of pyrolysis, measurements of the Arrhenius activation energies E_a for a reaction and its reverse are used to obtain one BDE value if the other is known.⁷ For example, in the reaction $\text{CH}_3\text{CH}_2-\text{H} + \text{H}_3\text{C}^\bullet \rightarrow \text{CH}_3\text{C}^\bullet\text{H}_2 + \text{H}-\text{CH}_3$, if $E_a(\text{forward}) = 32.7 \text{ kJ mol}^{-1}$ and $E_a(\text{reverse}) = 15.5$, then $\text{BDE}[\text{CH}_3\text{CH}_2-\text{H}] = \text{BDE}[\text{H}-\text{CH}_3] - (32.7 - 15.5)$.⁸ If $\text{BDE}[\text{CH}_3-\text{H}] = 439.3$ is known, then $\text{BDE}[\text{CH}_3\text{CH}_2-\text{H}] = 439.3 - 17.2 = 422.1 \text{ kJ mol}^{-1}$ is obtained in the temperature domain of the measurements. Measurements of the

forward and reverse rates of hydrogen abstractions by bromine atoms, that is, $\text{RH} + \text{Br}^* \rightleftharpoons \text{R}^* + \text{HBr}$, have been used to establish many $\text{BDE}[\text{R}-\text{H}]$ values. Hydrogen abstractions by iodine atoms have also been used. It must be kept in mind that bond dissociation enthalpies vary somewhat with temperature. For example, $\text{BDE}[\text{H}-\text{H}] = 436 \text{ kJ mol}^{-1}$ at 298 K but increases to 454 at 2000 K. This has important implications in understanding curvatures in the Arrhenius plots.⁹

Other experimental methods commonly used to establish values of BDE include calorimetry (enthalpy of combustion or hydrogenation), photoacoustic calorimetry (PAC) in solution, equilibrium studies and their temperature dependence, and enthalpies of isomerization.

Typical examples of calorimetry are the following: The enthalpy of formation of ethane is known to be $-84.0 \text{ kJ mol}^{-1}$ and the measured enthalpy of hydrogenation of ethylene to yield ethane is $\Delta H_{\text{rxn}} = -136.3$ at 298.15 K¹⁰; then the enthalpy of formation of ethylene is calculated from Hess's Law with $\Delta_f H^\circ[\text{H}_2] = 0.0$. The reaction is $\text{CH}_2 = \text{CH}_2 + \text{H}_2 \rightarrow \text{CH}_3\text{CH}_3$ and, by (2), $\Delta H_{\text{rxn}} = \Delta_f H^\circ[\text{CH}_3\text{CH}_3] - \Delta_f H^\circ[\text{CH}_2 = \text{CH}_2] - \Delta_f H^\circ[\text{H}_2]$. Substituting the known values leads to $-136.3 = -84.0 - \Delta_f H^\circ[\text{CH}_2 = \text{CH}_2] - (0.0)$. Solving yields $\Delta_f H^\circ[\text{CH}_2 = \text{CH}_2] = +52.3 \text{ kJ mol}^{-1}$. Similarly, for the hydrogenation of acetone with H_2 to yield 2-propanol, $\Delta H_{\text{rxn}} = -56.1 \pm 0.4 \text{ kJ mol}^{-1}$ by hydrogenation calorimetry.¹¹ If $\Delta_f H^\circ[\text{CH}_3\text{CH}(\text{OH})\text{CH}_3] = -272.8 \pm 0.8$ is known, substitution of these values into (2) yields $\Delta_f H^\circ[\text{CH}_3\text{C}(\text{O})\text{CH}_3] = -218.4 \pm 0.9 \text{ kJ mol}^{-1}$. An extensive compilation of enthalpies of hydrogenation is available.¹²

Equilibrium measurements as a function of temperature for $\text{A} \rightleftharpoons \text{B}$ yield ΔH_{rxn} and ΔS_{rxn} from a van't Hoff plot of $\ln K_e$ versus $1/T$. The slope is $-\Delta H_{\text{rxn}}/RT$ and the intercept is $\Delta S_{\text{rxn}}/R$ at the average temperature of the measurements. If $\Delta_f H^\circ[\text{A}]$ is known, $\Delta_f H^\circ[\text{B}]$ is thus calculated.

Studies of isomerizations can also lead to conclusions about relative stabilities of isomers or of bond energies. A classic example is the study of the cis-trans isomerization of 1,2-dideuterioethylene. Thermal isomerization between 460 and 540 °C indicated a requirement of $272 \pm 6 \text{ kJ mol}^{-1}$ for isomerization, presumably by allowing the p orbitals to become orthogonal thus breaking the π bond.¹³ There have been other theoretical estimates of the π -bond strength in ethylene and other

interpretations,^{14,15} but we favor of the 272 value for the π -bond strength (see below).

PAC measures BDEs in solution. Rapid heat release from a photoinitiated process produces a pressure wave, which is detected and quantified to yield the enthalpy of the process. The enthalpy is related to the strengths of bonds broken and made after appropriate corrections for solvent and volume effects. Many BDEs of bonds to H have been measured by PAC and they generally agree with those of gas-phase measurements when nonpolar solvents are used, even though early PAC values were somewhat low because corrections for effects of solvent were not adequate. A good account of the current PAC technique is available.¹⁶

Photoionization mass spectrometry (PIMS) is also used. A tunable light source establishes the threshold energy required to dissociatively ionize a target species, such as $\text{CH}_4 + h\nu_1 \rightarrow \text{H}_3\text{C}^+ + \text{H}^* + \text{e}^-$. Similarly, the ionization energy of the methyl radical is determined for $\text{H}_3\text{C}^* + h\nu_2 \rightarrow \text{H}_3\text{C}^+ + \text{e}^-$. Proper addition of the two measurements yields $\text{CH}_4 + h\nu_1 \rightarrow \text{H}_3\text{C}^* + \text{H}^* + h\nu_2$ and $\text{BDE}[\text{H}_3\text{C}-\text{H}] = h\nu_1 - h\nu_2$.¹⁷

Heterolytic bond cleavages are also used to obtain thermochemistry. These are basically measurements of acidity and redox potentials. In the case of a bond to hydrogen in molecule G-H, the heterolytic bond enthalpy is the enthalpy of deprotonation Δ_{acid} . The electron affinity of G, $EA[\text{G}]$, is obtained from $\text{G}^- + h\nu_1 \rightarrow \text{G}^* + \text{e}^-$, and the ionization energy of hydrogen $IE[\text{H}]$ from $\text{H}^* + h\nu_2 \rightarrow \text{H}^+ + \text{e}^-$. Then, $\text{BDE}[\text{G}-\text{H}] = \Delta_{\text{acid}} + EA[\text{G}] - IE[\text{H}]$.¹⁷ Bordwell and his group have obtained $\text{BDE}[\text{A}-\text{H}]$ values of weak acids AH in dimethylsulfoxide (DMSO) solvent by measuring the $\text{p}K_{\text{AH}}$ by the overlapping indicator method and the oxidation potential of A^- by cyclic voltammetry. Values of $\text{BDE}[\text{A}-\text{H}] = 5.73 \times \text{p}K_{\text{AH}} + 96.7 \times E_{\text{ox}}[\text{A}^-] + 306.7 \text{ kJ mol}^{-1}$ were reported to be in reasonable agreement with gas-phase BDE values at 298.15 K, especially when a correction for solvent effects was made.^{18,19}

Bond dissociation enthalpies are commonly calculated from known enthalpies of formation. For homolytic bond cleavage $\text{A}-\text{B} \rightarrow \text{A}^* + \text{B}^*$, the bond dissociation enthalpy is calculated by (3).

$$\text{BDE}[\text{A}-\text{B}] = \Delta_f H^\circ[\text{A}^*] + \Delta_f H^\circ[\text{B}^*] - \Delta_f H^\circ[\text{AB}] \quad (3)$$

For example, $\text{BDE}[\text{CH}_3\text{CH}_2\text{-OH}]$, which is ΔH_{rxn} for the reaction $\text{CH}_3\text{CH}_2\text{OH} \rightarrow \text{CH}_3\text{CH}_2^\bullet + \text{HO}^\bullet$, can be calculated if the enthalpies of formation of ethanol, ethyl radical, and hydroxyl radical are known: $\Delta H_{\text{rxn}} = \text{BDE}[\text{CH}_3\text{CH}_2\text{-OH}] = \Delta_f H^\circ[\text{CH}_3\text{C}^\bullet\text{H}_2] + \Delta_f H^\circ[\text{HO}^\bullet] - \Delta_f H^\circ[\text{CH}_3\text{CH}_2\text{OH}]$. Thousands of $\Delta_f H^\circ$ values of closed-shell species have been reported. An extensive compilation is available from the National Institute of Standards and Technology (NIST) for free on the Web.²⁰ Another readily available source of BDE and $\Delta_f H^\circ[\text{R}^\bullet]$ is the “Rubber Handbook.”²¹ Two monographs by Luo are also valuable.^{22,23} An older version of the NIST database contains some values not included subsequently.²⁴ Pedley’s monograph is still a good source of reliable values.²⁵ Experimental enthalpies of formation of radical species and theoretically calculated values are fewer and generally less accurate than those of closed-shell species.

2 EXPERIMENTAL AND *AB INITIO* VALUES

Experimental measurements of $\Delta_f H^\circ$ and of BDE values are difficult to perform and there have been some significant revisions of the values of common compounds in the last 40 years. For aldehydes, $\text{BDE}[\text{RC}(\text{O})\text{-H}] = 322 \text{ kJ mol}^{-1}$ was being quoted in 1971.²⁶ A higher value of 367 was suggested in 1975²⁷; the currently quoted value is 376.²⁰ Similarly, in 1972 it was suggested that the value of $\text{BDE}[\text{H}_2\text{N-H}] = 431 \text{ kJ mol}^{-1}$ used at the time was too low to account for rates of hydrogen abstractions from ammonia and a minimum of 439 was recommended²⁸; the currently quoted value is 454.²⁰ Values in current use are probably more reliable mostly because of two reasons: better instrumentation and the ability to perform *ab initio* calculations of sufficient accuracy to warn of possible large errors in experimental determinations (see **Radical Stability—Thermochemical Aspects**).

Ab initio methods have improved to the point of where G3 model calculations obtain values for $\Delta_f H^\circ$ of closed-shell species with accuracies usually better than $\pm 6\text{--}8 \text{ kJ mol}^{-1}$, which is of the same order of magnitude as in many thermochemical measurements.²⁹ A modification

denoted G3(MP2)-RAD is successful in producing $\Delta_f H^\circ$ values for many radicals with similar accuracies.^{30,31} These are high-level composite methods that include some empirical correction terms (high-level corrections, HLC). These types of calculations are quite demanding of computer resources and this places practical limits on the size of the molecules that can be treated.

Table 1 provides a listing of many of the available enthalpies of formation of radical species $\text{R}^\bullet$, along with $\text{BDE}[\text{R-H}]$, $\text{BDE}[\text{R-CH}_3]$, and $\text{BDE}[\text{R-Cl}]$, if the BDE values are available. Throughout this article, all BDE and $\Delta_f H^\circ$ values appearing without specific attribution are from Refs 20–24. More than one value for a particular entry is often available in the literature, and a subjective judgment of reliability had to be made by the author for selecting one. An empty cell in the table indicates that a value was not located in the literature.

3 REGULARITIES IN ENTHALPIES OF FORMATION

There are remarkable regularities in enthalpies of formation and in bond dissociation enthalpies of organic molecules. As a result, empirical schemes exist for estimating gas-phase enthalpies of formation with empirical parameters of group additivity (GA) found by global fittings to a large number of molecules. Many such approaches generally succeed. The GA scheme of Benson is one of the better known.^{55,56} Each group, depending on its neighbors, contributes to the stability of a molecule a specific amount, irrespective of the overall molecular structure. The original scheme was subsequently updated.⁵⁷ This widely known and used GA scheme has been implemented in the NIST database 69.^{20,58} At the site’s homepage on the Web, under Models and Tools, one of the bullets is “Group Additivity Based Estimates.” Clicking on this produces a new menu. Clicking on “Use applet to draw a structure” produces a pallet on which one can draw a desired molecule by selecting the appropriate atoms from a menu and pressing “Done” when finished. The program generates a GA-based value of $\Delta_f H^\circ$ of the molecule and is generally quite accurate, generally to within $\pm 6 \text{ kJ mol}^{-1}$ or better. The procedure is quite easy and avoids the drudgery of looking up extensive tables of group increments,

Table 1 Literature values of standard enthalpies of formation (kJ mol^{-1}) of radicals $\text{R}^\bullet$ and BDE of R-H , R-CH_3 , and R-Cl , when available.

Open shell (radical, $\text{R}^\bullet$)	$\Delta_f H^\circ[\text{R}^\bullet]$	BDE[R-H]	BDE[R-Me]	BDE[R-Cl]

next-neighbor effects, ring strains, resonance and conjugation effects, and so on.

Regularities in the enthalpies of combustion of linear alcohols were noted as early as 1932 by Rossini.⁵⁹ Luo and Holmes noted the constancy of the relationship between vinyl and phenyl derivatives, irrespective of the nature of X: $\Delta_f H^\circ[\text{CH}_2=\text{CHX}] = \Delta_f H^\circ[\text{C}_6\text{H}_5\text{X}] - (29.7 \pm 6.7)$.⁶⁰ Improvements were made to Benson's group additivity scheme, for example, to include parameters for multichloro-substituted alkanes and alkenes.⁶¹ The Reyniers group established Benson-type GA values for the enthalpy of formation of hydrocarbons and their radicals based on *ab initio* (CBS-QB3) standard enthalpies of formation of 233 compounds, obtaining 95 GA values.⁶² Radical enthalpies of formation were predicted on the basis of the fitted GA values for many species for which there were no experimental data. Other additivity schemes have been proposed recently for hydrocarbons and their radicals.^{63,64} It appears clear that no significance can be attached to the group values obtained from empirical fitting schemes. If they are successful, then they have been shown to map onto each other.⁶⁵ Allinger's successful molecular mechanics approach (MMX) also establishes transferable structural regularities by examining a large variety of molecules with known properties.^{66,67}

3.1 Hydrocarbons and Their Carbon-Centered Radicals

Probably the simplest GA approach for calculating enthalpies of formation of hydrocarbons is (4), which requires the counting of the number of hydrogens of each type present: n_1 of primary (1°) aliphatic hydrogens (H's bonded to sp^3 carbon), n_2 of 2° aliphatic H's, n_3 of 3° aliphatic H's, n_4 of vinyl H's, n_5 of H's missing from C=C groups, n_6 is the number of terminal alkynes including acetylene, n_7 is the number of internal alkynes, n_8 is the number of H's missing from benzene rings, and n_9 is the number of benzene rings.⁶⁸

$$\begin{aligned} \Delta_f H^\circ = & -14.00n_1 - 10.42n_2 - 6.653n_3 + 13.12n_4 \\ & + 23.43n_5 + 227.7n_6 + 231.4n_7 \\ & + 9.079n_8 + 82.93n_9 \text{ kJ mol}^{-1} \end{aligned} \quad (4)$$

Equation (4) does not take account of "special effects." Such effects are (i) steric strain, as exists in di-*tert*-butyl (2,2,3,3-tetramethylbutane); (ii) angle strain, as exists in cyclopropane; (iii) conjugation stabilization, as in 1,3-butadiene; and (iv) resonance stabilization by electron delocalization, as exists only with the groups –OH, –OR, –NH₂, and –NR₂ connected to sp^2 - and sp -hybridized atoms (e.g., carbon, nitrogen of NO₂, boron of BH₂).

When (4) is applied to systems that are subject to "special effects," the calculated result differs from the experimental value by the magnitude of the special effect. The calculated $\Delta_f H^\circ$ [di-*tert*-butyl] is -251.9 versus the experimental value of -226.2 kJ mol⁻¹. The strain energy of the compound is 25.7 kJ mol⁻¹. Similarly, when (4) is used for 1,3-butadiene, the value calculated via (4) is 125.6 versus 108.8 ± 0.8 experimental. Stabilization by conjugation amounts to 16.7 kJ mol⁻¹.

The coefficients of (4) are not based on global fittings to a large set of various known compounds, as is done by well-known approaches such as Benson's GA or by Allinger's molecular mechanics. The coefficients of each term were obtained from a typical molecule in each case: c_1 from 2,2-dimethylpropane, c_2 from butane, c_3 from 2,4-dimethylpentane, c_4 from ethylene, c_5 from *trans*-2-butene, c_6 from 1-butyne, c_7 from 2-butyne and 2-pentyne, c_8 from toluene, and c_9 from benzene. Enthalpies of formation of hundreds of hydrocarbons have been calculated very accurately. The weakness of (4) in not accounting for special effects is counterbalanced by its simplicity and remarkable accuracy. For example, the value of $c_1 = -14.00$ per primary aliphatic H obtained from the 12 hydrogens of neopentane yields $\Delta_f H^\circ$ [ethane] = $6 \times (-14.00) = -84.0$ versus the experimental value of -84.0 ± 0.4 kJ mol⁻¹. The value of $c_2 = -10.42$ obtained from the four secondary aliphatic Hs of butane yields $\Delta_f H^\circ$ [cyclohexane] = $12 \times (-10.42) = -125.0$ versus the experimental value of 124.6 ± 1.8 kJ mol⁻¹. Despite the simplicity of (4), this type of accuracy is maintained to quite large molecules and yields the correct $\Delta_f H^\circ$ values for species such as the *trans*-decalin (decahydronaphthalene), 3-methyl-1,4-pentadiene, 1,5-heptadiyne, cyclohexylbenzene, and so on. The performance with decalin is typical: there are 16 secondary hydrogens ($n_2 = 16$), 2 tertiary hydrogens ($n_3 = 2$), all other n_i are zero for (4).

$\Delta_f H^\circ[\text{decalin}] = (-10.42) \times 16 + (-6.653) \times 2 = -180.0$ versus the experimental value $\Delta_f H^\circ[\text{trans-decalin}] = -182.2 \pm 2.3 \text{ kJ mol}^{-1}$. Evidently, the *trans* isomer is strain-free. Experimental $\Delta_f H^\circ[\text{cis-decalin}] = -169.2 \pm 2.3$, indicating strain of 10.8 kJ mol^{-1} . High-level *ab initio* calculations for such large molecules would require considerable computer resources and could be no more accurate. Equation (4) requires two multiplications and one addition. Nature is frugal in its patterns. Equation (4) is easily extended to apply to species other than hydrocarbons in a simple fashion.

An extension of (4) is used for carbon-centered radicals derived from hydrocarbons. Regular patterns exist for enthalpies of formation of alkyl radicals that are not allylic, propargylic, or benzylic. For species containing a strained ring, such as the primary alkyl radical cyclopentylmethyl (*cyclo*-C₅H₉-C[•]H₂), the experimental enthalpy of formation of the parent hydrocarbon methylcyclopentane is used. Standard enthalpies of formation of primary, secondary, and tertiary alkyl radicals that are not inside a strained ring can be obtained accurately from the enthalpies of formation of their parent hydrocarbons by (5)–(7).⁶⁹ Agreement with experimental values is always within the experimental uncertainty for 13 primary alkyl radicals found in the literature.

$$\Delta_f H^\circ[\text{RC}^\bullet\text{H}_2] = \Delta_f H^\circ[\text{RCH}_3] + 204.6 \quad (5)$$

$$\Delta_f H^\circ[\text{R}_2\text{C}^\bullet\text{H}] = \Delta_f H^\circ[\text{R}_2\text{CH}_2] + 194.6 \quad (6)$$

$$\Delta_f H^\circ[\text{R}_3\text{C}^\bullet] = \Delta_f H^\circ[\text{R}_3\text{CH}] + 184.5 \quad (7)$$

Table 2 provides $\Delta_f H^\circ$ values of the hydrocarbon precursors obtained by (4), $\Delta_f H^\circ$ of their carbon radicals by (5)–(7), and corresponding literature values when found. The agreement between the calculated and the literature values in Table 2 demonstrates the reliability of the calculated $\Delta_f H^\circ[\text{R}^\bullet]$ and allows confident predictions to be made regarding other radicals of interest for which no experimental data exist. Values are also provided for some radicals for which no thermodynamic data could be found.

The instabilities caused by removal of 1° hydrogen to form 1° allyl, propargyl, or benzyl radicals are smaller than $204.6 \text{ kJ mol}^{-1}$ because of resonance stabilization of the odd electron of

such radicals. The instability of the allyl radical relative to the parent hydrocarbon propene is $\Delta_f H^\circ[\text{CH}_2=\text{CHC}^\bullet\text{H}_2] - \Delta_f H^\circ[\text{CH}_2=\text{CHCH}_3] = 150.3$. For propargyl radical, the difference is 163 and for benzyl radical 157. Hence, the vinyl group is the most effective of the three in stabilizing an odd electron on adjacent carbon, followed by phenyl, with the ethynyl group being the least effective.

Cyclization of radicals of the type of 5-hexen-1-yl to cyclohexyl or to cyclopentylmethyl is a reaction of the type used as a “radical clock” and is a useful tool for the synthesis of complex molecules.^{72,73} A review is also available.⁷⁴ Houk *et al.* have performed high level *ab initio* calculations (G3MP2B3) of the thermodynamics of cyclization of the 5-hexen-1-yl radical.⁷⁵ The total enthalpies calculated, H^{298} , are in units of hartrees (E_h) and pertain to the formation of the species from the naked nuclei and electrons ($2625.5 \text{ kJ mol}^{-1}$ per hartree). The reported values are shown in the first line of Figure 1.

Relative to 5-hexen-1-yl, the cyclohexyl radical is more stable by $-0.032485 E_h$ or 85.3 kJ mol^{-1} with a stated uncertainty of ± 4.2 (path *a*). The cyclopentylmethyl radical is more stable than 5-hexen-1-yl by $-0.022560 E_h$ or $-59.2 \pm 4.2 \text{ kJ mol}^{-1}$ (path *b*). An alternative approach to obtaining the energetics of these cyclizations is shown in Figure 1 the chemical structures and is as follows. The standard enthalpy of formation of the cyclohexyl radical is known, $\Delta_f H^\circ[\text{C}_6\text{H}_{11}^\bullet] = 75.3 \pm 6.3 \text{ kJ mol}^{-1}$. This is not

Figure 1 Energetics of cyclization of 5-hexen-1-yl radical. First line: total enthalpy of formation in hartrees by G3MP2B3. Second line: stabilizations in hartrees relative to 5-hexen-1-yl. Third line: relative stabilizations in kilojoules per mole. First line below the chemical structures: standard enthalpies of formation in kilojoules per mole. Second line: relative stabilizations in kilojoules per mole.

Table 2 Standard enthalpies of formation of hydrocarbon precursors obtained by (4), those of 1°, 2°, and 3° carbon radicals by (5)–(7), and literature values found (kJ mol^{−1}).

^a Reference 20, unless indicated otherwise.^b Reference 22.^c Reference 24.^d Reference 70.^e Reference 71.^f $\Delta_f H$ [R[•]] not found.^g Because the cyclopentane ring is strained, the experimental value of $\Delta_f H$ [methylcyclopentane] is used.

the case for the other two 1° radicals, but they can be calculated easily. The precursor hydrocarbon of the 5-hexen-1-yl radical is 1-hexene with $\Delta_f H^\circ[\text{CH}_2=\text{CH}(\text{CH}_2)_3\text{CH}_3] = -41.7$ kJ mol^{−1} calculated by (4) (experimental -42 ± 2). Hence, $\Delta_f H^\circ[\text{CH}_2=\text{CHCH}_2\text{CH}_2\text{C}^\bullet\text{H}_2] = -41.7 + 204.6 = 162.9$. The precursor hydrocarbon for the cyclopentylmethyl radical is methylcyclopentane, with experimental enthalpy of formation $\Delta_f H^\circ[\text{cyclo-C}_5\text{H}_9\text{CH}_3] = -106.0$. Hence, $\Delta_f H^\circ[\text{cyclo-C}_5\text{H}_9\text{C}^\bullet\text{H}_2] = -106.0 + 204.6 = 98.7$. By the

alternative approach presented here, cyclohexyl is more stable by -87.6 kJ mol^{−1} (path *a*) relative to 5-hexen-1-yl and cyclopentylmethyl is more stable by -64.2 (path *b*). The *ab initio* approach and the above simple calculation yield essentially the same results within reasonably expected uncertainties.

With ethane as the parent hydrocarbon, the enthalpy of formation of the diradical species C[•]H₂C[•]H₂ can be calculated by (4) and (5) as $\Delta_f H^\circ[\text{CH}_3\text{CH}_3] + 2 \times 204.6 = -84 + 409.2 = 325.2$ kJ mol^{−1}. The diradical would collapse to

ethylene, $\Delta_f H^\circ[\text{CH}_2=\text{CH}_2] = 52.5$, thereby releasing $272.2 \text{ kJ mol}^{-1}$. This value is identical to the energy of the π bond of ethylene as determined from the cis–trans isomerization of dideuterioethylene, $272 \pm 6 \text{ kJ mol}^{-1}$.

3.2 Alcohols and Alkoxy Radicals

Enthalpies of formation of other common organic species can also be obtained with high accuracy by similar approaches that reflect existing regularities.

Enthalpies of formation of primary, secondary, and tertiary alcohols may be obtained accurately by (8)–(10). $\Delta_f H^\circ$ of the parent hydrocarbons may be calculated by (4) or taken from the literature.⁶⁹ In case of strained species, the experimental value of $\Delta_f H^\circ$ of the hydrocarbon precursor is used. Equations (8)–(10) are also valid for allylic, propargylic, and benzylic alcohols.

$$\Delta_f H^\circ[\text{RCH}_2\text{OH}] = \Delta_f H^\circ[\text{RCH}_3] - 150.6 \pm 2.5 \quad (8)$$

$$\Delta_f H^\circ[\text{R}_2\text{CHOH}] = \Delta_f H^\circ[\text{R}_2\text{CH}_2] - 168.2 \pm 0.8 \quad (9)$$

$$\Delta_f H^\circ[\text{R}_3\text{COH}] = \Delta_f H^\circ[\text{R}_3\text{CH}] - 179.9 \quad (10)$$

Examples of $\Delta_f H^\circ$ values of primary alcohols calculated via $\Delta_f H^\circ[\text{RCH}_3]$ of (4), are as follows with the experimental values in parentheses: 1,2-ethanediol, -384.9 (-394.6 , -387.9 , -390.4 , -387.4); neopentyl alcohol, -318.4 (-318.4); 1-decanol, -401.2 (-393.3 ± 12.6); and allyl alcohol -129.7 (-123.8 ± 1.7 , -128.4 ± 2.9^{11}). In all, 27 available values of primary alcohols were calculated satisfactorily.⁶⁹

For secondary alcohols, with $\Delta_f H^\circ[\text{RR}'\text{CH}_2]$ calculated by (4), some examples are as follows with experimental values in parentheses: cyclohexanol, -293.2 (-288.7 ± 8.4); 2,3-butanediol, -461.9 (-462.3). For 1,2,3-propanetriol, $\Delta_f H^\circ$ [propane] = -104.8 and twice 150.6 ± 2.5 is subtracted for the two 1° alcohol functions and 168.2 ± 0.8 for the 2° alcohol to yield 574.2 ± 3.5 versus experimental 577.8 ± 1.3 and 577.0 . For the strained cyclopentanol, with the experimental $\Delta_f H^\circ$ [cyclopentane] = -76.6 ± 0.8 , the calculation obtains $\Delta_f H^\circ$ [cyclopentanol] = -244.8 versus

Figure 2 Plot of the stabilization constants of (8)–(10) and of methyl for converting enthalpies of formation of the parent hydrocarbons to those of methyl, primary, secondary, and tertiary alcohols versus the dipole contribution to BDE[R–OH] given by Pauling's $96.23 \times (\chi[\text{R}] - \chi[\text{OH}])^2$.

experimental -243.1 and -242.7 ± 1.6 . Secondary allylic, propargylic, and benzylic alcohols are calculated accurately. The 27 experimental values for 2° alcohols that are available in the literature are matched well.⁶⁹

For tertiary alcohols, the pattern is $\Delta_f H^\circ[\text{RR}'\text{R}''\text{OH}] = \Delta_f H^\circ[\text{RR}'\text{R}''\text{OH}] - 179.9$ and good agreements are obtained with the few available experimental values.⁶⁹

For the unique methane–methanol transformation, the stabilizing constant is $\Delta_f H^\circ[\text{CH}_3\text{OH}] - \Delta_f H^\circ[\text{CH}_4] = -205 - (-74.9) = -130.1 \text{ kJ mol}^{-1}$. Figure 2 shows a plot of the four stabilization constants for these alcohols versus the dipole contribution to BDE[R–OH] given by Pauling's $96.23 \times (\chi[\text{R}] - \chi[\text{OH}])^2$, which will be discussed below. An excellent linear dependence is seen with a correlation coefficient of 0.99999.

There are not many experimental values of the enthalpies of formation of alkoxy radicals and those that exist are not known as accurately as those of carbon radicals. There are quite disparate values in the literature of the past decade and there is no self-consistent set. For species in which the oxygen bearing the odd electron is connected to an sp^3 carbon, unpublished work from this laboratory indicates that enthalpies of formation

can be estimated by $\Delta_f H^\circ[\text{RO}^\bullet] = \Delta_f H^\circ[\text{ROH}] + (222 \pm 6) \text{ kJ mol}^{-1}$. Table 3 shows the calculated $\Delta_f H^\circ$ of the precursor alcohols, the calculated values of the alkoxy radicals, and corresponding literature values. The table also provides estimates for alkoxy radicals for which no values were found in the literature: neopentyloxy, the doubly allylic 1,4-pentadien-3-oxyl, and the cumyloxy radical that has often been used as a hydrogen abstractor.

There are some values of enthalpies of formation available for oxyl radicals having the oxygen on an sp^2 carbon. For vinyl alcohol, $\Delta_f H^\circ[\text{CH}_2=\text{CHOH}] = -128$ and $\Delta_f H^\circ[\text{CH}_2=\text{CHO}^\bullet] = 10.5$.⁸⁰ For phenol, $\Delta_f H^\circ[\text{C}_6\text{H}_5\text{OH}] = -96.4$ and $\Delta_f H^\circ[\text{C}_6\text{H}_5\text{O}^\bullet] = 49.7 \pm 1 \text{ kJ mol}^{-1}$.⁴⁹

BDE[O–H] values, but not enthalpies of formation, are available for some other important precursors of oxyl radicals. For the antioxidant α -tocopherol, BDE[O–H] = $327.3 \pm 1 \text{ kJ mol}^{-1}$.⁸¹

The persistent *N*-oxyl radical 2,2,6,6-tetramethyl-1-piperidinyloxy (TEMPO) is often used to bring about commercially important “living free-radical polymerization” (LFRP, see **Nitroxide-Mediated Polymerization and its Applications**). In 1979, Rizzardo *et al.* showed

that vinyl free-radical polymerization can be controlled by reversible capping with nitroxides, because of the weak C–O bond formed in the capping reaction⁸²; subsequent work provided valuable additional information.^{83,84} In 1993, Georges *et al.* discussed the preparation of low-polydispersity polystyrene by LFRP regulated by nitroxides, and this stimulated widespread research in this area.⁸⁵ Measurements of the strength of the O–C bond formed in the capping process ($\text{R}_2\text{NO–CR}_3$) have been made via kinetic studies. Results relevant to polymerization of styrene have been reported for TEMPO– CH_2Ph , TEMPO– $\text{CH}(\text{CH}_3)\text{Ph}$, and TEMPO– $\text{C}(\text{CH}_3)_2\text{Ph}$: BDE[O–C] = 128.9, 118.8, and $102.9 \text{ kJ mol}^{-1}$, respectively. For mimicking a growing polystyrene polymer, the secondary benzyl radical result is the best model.⁸⁶ Theoretical calculations (G3(MP2)-RAD) have yielded, after adjustment to 298 K, BDE [TEMPO–R] = 204 for $\text{R} = \text{CH}_3$, 218.1 for $\text{R} = \text{CH}_2\text{CH}_3$, 213 for $\text{R} = \text{CH}(\text{CH}_3)_2$, and 221 for $\text{R} = \text{C}(\text{CH}_3)_3$.⁸⁷ A weak O–C bond has also been reported for a structurally simpler alkoxyamine, BDE[(CH_3CH_2) $_2\text{NO–CH}(\text{CH}_3)\text{Ph}$] = 143.5 ± 6.7 .⁸⁸

Table 3 Standard enthalpies of formation of alcohol precursors, those of the corresponding alkoxy radicals by $\Delta_f H^\circ[\text{RO}^\bullet] = [\text{ROH}] + 222$, and literature values (kJ mol^{-1}).

^g No values found in the literature for neopentyloxy, the doubly allylic 1,4-pentadien-3-oxyl, and cumyloxy radicals.

There are several reports for BDE[O–H] of the TEMPO precursor *N*-hydroxy-2,2,6,6-tetramethylpiperidine. BDE[O–H] = 288.7 in benzene solvent,⁸⁹ 299.2 ± 2.1 in acetonitrile, 292.9 ± 3.8 in benzene,⁵² 291.6 in DMSO,⁹⁰ and 293.3 ± 1.6 in heptane.⁹¹ The value in heptane solvent should be quite similar to the gas-phase value. Relative to TEMPO–H, di-*tert*-butylhydroxylamine has an O–H BDE weaker by 13 kJ mol^{−1} resulting in BDE[(*tert*-Bu)₂NO–H] = 280.⁹²

Another type of *N*-oxyl radicals has been found to be an effective catalyst in the oxidation of organic compounds by molecular oxygen under mild conditions in the presence of cobalt salts (see **Nitroxides in Synthetic Radical Chemistry**).^{93,94} *N*-Hydroxyphthalimide (NIPI) is effective in this respect by giving rise to the phthalimide *N*-oxyl (PINO) radical. BDE[O–H] = 368.6 ± 2.5 kJ mol^{−1} has been obtained by using the electron paramagnetic resonance (EPR) radical equilibration technique⁹⁵; a semiempirical calculation based on a thermodynamic cycle gave 374.9 ± 10.0.⁹⁶ A considerably lower value of BDE[O–H] = 349.3 ± 4.2 for NIPI has also been reported from theoretical calculations.⁹⁷ Functionalization of organic compounds by NIPI catalysis has been reviewed.⁹⁸ *N*-Methylbenzohydroxamic acid has been used to selectively synthesize lipid hydroperoxides and alcohols. It has BDE[O–H] = 331.4 kJ mol^{−1}, which is intermediate between those of TEMPO–H and NHPI.⁹⁹

Hydroxylamine and H₂NO•, the simplest *N*-oxyl radical, have also been studied experimentally and by theoretical calculations. Experimental $\Delta_f H^\circ$ [H₂NOH] = 50 ± 10 kJ mol^{−1}.¹⁰⁰ By (Coupled-Cluster Singles and Doubles model with perturbative Triplets) CCSD(T)-type calculations, extrapolated to the CBS limit, $\Delta_f H^\circ$ [H₂NOH] = 42.3 ± 1.3, $\Delta_f H^\circ$ [H₂NO•] = 66.9 ± 3.3 and $\Delta_f H^\circ$ [HN•OH] = 96.7 ± 3.3 kJ mol^{−1}.¹⁰¹ The theoretical values lead to BDE[H₂NO–H] = 327.2 and BDE [HONH–H] = 356.9. A study of the oxidation of hydroxylamine and the kinetics of the products led to a BDE[H₂NO–H] = 318 ± 4.2 and BDE[HONH–H] = 341 ± 2.1 kJ mol^{−1}.¹⁰²

3.3 Hydroperoxides and Hydroperoxyl Radicals

Hydroperoxides and peroxy radicals are important in combustion, autoxidations of oleates and

linoleates, DNA damage, and so on. Existing experimental and theoretical values of enthalpies of formation show wide scatter. The regularities in enthalpies of formation of primary, secondary, and tertiary hydroperoxides allow their accurate calculation by (11)–(14), when the –OOH functionality is not connected to sp²- or sp-hybridized carbons.

$$\Delta_f H^\circ [\text{CH}_3\text{OOH}] = \Delta_f H^\circ [\text{CH}_4] - 55.6 \quad (11)$$

$$\Delta_f H^\circ [\text{RCH}_2\text{OOH}] = \Delta_f H^\circ [\text{RCH}_3] - 76.6 \quad (12)$$

$$\Delta_f H^\circ [\text{R}_2\text{CHOOH}] = \Delta_f H^\circ [\text{R}_2\text{CH}_2] - 93.3 \quad (13)$$

$$\Delta_f H^\circ [\text{R}_3\text{COOH}] = \Delta_f H^\circ [\text{R}_3\text{CH}] - 105.8 \quad (14)$$

$\Delta_f H^\circ$ of the parent hydrocarbons may be calculated by (4) or taken from the literature. Equations (11)–(14) are also valid for allylic, propargylic, and benzylic hydroperoxides. Table 4 shows the calculated $\Delta_f H^\circ$ [ROOH] and existing literature values. The table also provides values for some hydroperoxides for which none was found in the literature. There do not appear to be any experimental values available for enthalpies of formation of secondary allylic hydroperoxides, which are of interest in peroxidations or autoxidations of unsaturated lipids; 2-hydroperoxy-3-butene is included as a model for them. For polyunsaturated lipids, the doubly allylic 3-hydroperoxypenta-1,4-diene is also calculated.

A plot of the stabilization constants of (11)–(14) versus the dipole contribution to BDE[R–OOH] given by Pauling's $96.23 \times (\chi[\text{R}] - \chi[\text{OOH}])^2$ yields a straight line with a correlation coefficient of 0.9999.

For a hydroperoxide function connected to sp²- or sp-hybridized carbon, the following have been reported from theoretical calculations based on B3LYP/6-311G(d,p).¹⁰⁵ $\Delta_f H^\circ$ [CH₂ = CHOOH] = −40.3, $\Delta_f H^\circ$ [C₆H₅OOH] = −11.2, and $\Delta_f H^\circ$ [HC≡COOH] = 176.8 kJ mol^{−1}.

Enthalpies of formation of peroxy radicals, which are the chain-propagating species in autoxidations, have also been studied but the reported results are often inconsistent. A consistently accurate set of enthalpies of formation is obtained by $\Delta_f H^\circ$ [ROO•] = $\Delta_f H^\circ$ [ROOH] + 140 kJ mol^{−1}, where R is any sp³-hybridized carbon. Values of $\Delta_f H^\circ$ [ROO•] so obtained are given in Table 5, along with corresponding literature values. Agreement between the values calculated here and those in the literature should lend confidence

Table 4 Standard enthalpies of formation of precursors by (4), those of their hydroperoxides by (11)–(14), and literature values (kJ mole^{−1}).

ROOH	$\Delta_f H^\circ$ [RH]	Calculated $\Delta_f H^\circ$ [ROOH]	Literature $\Delta_f H^\circ$ [ROOH]

to the methods used. Particularly noteworthy is the agreement with the experimental value for the enthalpy of formation of the doubly allylic peroxy radical (CH₂=CH)₂CHOO•, 151.4, calculated versus 144 ± 11 experimental.¹⁰⁸ For bonds to sp² carbon, $\Delta_f H^\circ$ [CH₂=CHOO•] = 101.8 ± 1.8 and $\Delta_f H^\circ$ [C₆H₅OO•] = 130.9 ± 2.0 have been reported.¹⁰⁵ Hence, BDE[CH₂=CH–OO•] = 192.7 ± 5.3 and BDE[C₆H₅–OO•] = 208.1 ± 8.2 kJ mol^{−1}.

Also of interest are BDE values of species involved in combustion and autoxidation, and there are literature reports of some BDE[R–OOH] and BDE[R–OO•]. Their values BDEs can be calculated with $\Delta_f H^\circ$ [HOO•] = 12.3 kJ mol^{−1} and $\Delta_f H^\circ$ [R•] from Tables 1 and 2 the established $\Delta_f H^\circ$ [ROOH] and $\Delta_f H^\circ$ [ROO•] by ((15) and (16)).

$$\begin{aligned} \text{BDE}[R - \text{OOH}] &= \Delta_f H^\circ[R^\bullet] + \Delta_f H^\circ[\text{HOO}^\bullet] \\ &\quad - \Delta_f H^\circ[\text{ROOH}] \end{aligned} \quad (15)$$

$$\begin{aligned} \text{BDE}[R - \text{OO}^\bullet] &= \Delta_f H^\circ[R^\bullet] + \Delta_f H^\circ[\text{O}_2] \\ &\quad - \Delta_f H^\circ[\text{ROO}^\bullet] \end{aligned} \quad (16)$$

The results are given in Table 6. The calculated BDE[R–OO•] for R = secondary allylic radical is sufficiently strong at 95 kJ mol^{−1} for the R• and •O–O• to react near room temperature forming the peroxy radical that propagates chain reactions. However, the calculated BDE of 53.2 for R = secondary doubly allylic radical is sufficiently weak to indicate that the equilibrium R• + •O–O• ⇌ ROO• may not be particularly favorable for the forward reaction at ambient temperatures. This is consistent with the report that at 333 K (60 °C) the rate of disappearance of (CH₂=CH)₂C•H radicals becomes independent of O₂ pressure and the rate of the reverse reaction becomes so fast that little net reaction occurs between the radical and O₂.¹⁰⁸ The calculated BDE is in excellent agreement with the reported experimental value of 56 ± 5 kJ mol^{−1}. For oxygen bonded to sp²- and sp-hybridized carbons, reported values are¹⁰⁵ BDE[R–OOH] = 360.1 ± 5.1, 393.1 ± 2.1, and 360.1 ± 4.1 kJ mol^{−1} for R = vinyl, ethynyl, and phenyl, respectively; also, BDE[R–OO•] = 198.2 ± 5.0, 204.6 ± 1.7, and 209.7 ± 2.7 kJ mol^{−1} for R = vinyl, ethynyl, and phenyl, respectively.

3.4 Amines and Nitrogen-Centered Radicals

Enthalpies of formation of primary amines with the amino group connected to an sp³-hybridized carbon also follow very regular patterns.⁶⁹ For the -NH₂ group connected to an sp³-hybridized carbon, enthalpies of formation are accurately calculated by (17)–(20).

$$\Delta_f H^\circ[\text{CH}_3\text{NH}_2] - \Delta_f H^\circ[\text{CH}_4] = 51.5 \quad (17)$$

$$\Delta_f H^\circ[\text{RCH}_2\text{NH}_2] = \Delta_f H^\circ[\text{RCH}_3] + 36.4 \quad (18)$$

$$\Delta_f H^\circ[\text{RR}'\text{CHNH}_2] = \Delta_f H^\circ[\text{RR}'\text{CH}_2] + 20.9 \quad (19)$$

$$\Delta_f H^\circ[\text{RR}'\text{R}''\text{CNH}_2] = \Delta_f H^\circ[\text{RR}'\text{R}''\text{CH}] + 12.1 \quad (20)$$

For the unique methylamine, using experimental values, $\Delta_f H^\circ[\text{CH}_3\text{NH}_2] - \Delta_f H^\circ[\text{CH}_4] = -23.4 - (-74.9) = 51.5 \text{ kJ mol}^{-1}$ as the destabilization ensuing from the formation of the nitrogen-centered radical.

For the available $\Delta_f H^\circ$ of 20 amines of the type RCH₂NH₂, (18) yields results within the uncertainty of reported values. For example, $\Delta_f H^\circ[2\text{-aminoethanol}]$ is obtained from $\Delta_f H^\circ[\text{CH}_3\text{CH}_3]$ by subtracting 150.6 for the 1° alcohol function and adding 36.4 for -NH₂ group connected to 1° carbon. The calculated result of -197.9 is well within experimental uncertainty of reported measurements of -200.8 and -201.7. For benzylamine, the calculated $\Delta_f H^\circ = 86.2$ versus experimental 87.9 ± 2.9 and 83.7 ± 2.9 .

For the -NH₂ group connected to 2° carbon, $\Delta_f H^\circ[\text{RR}'\text{CHNH}_2] = \Delta_f H^\circ[\text{RR}'\text{CH}_2] + 20.9 \text{ kJ mol}^{-1}$. Available literature values for such amines are matched well by the calculation even for quite large molecules. For amphetamine (2-amino-1-phenylpropane) as an example, the hydrocarbon precursor is propylbenzene with $\Delta_f H^\circ = 8.3$ by (4) and $\Delta_f H^\circ[\text{C}_6\text{H}_5\text{CH}_2\text{CH}(\text{NH}_2)\text{CH}_3] = 8.3 + 20.9 = 29.2$ versus experimental 29.3. The gas-phase enthalpy of formation of norephedrine (2-amino-1-phenyl-1-propanol) is not available

Table 6 Calculated BDE[R–OOH] by (15) with literature values and calculated BDE[R–OO•] by (16) with literature values (kJ mol^{−1}).

^aReference 21.^bSame as footnote *c* of Table 4.^cReference 105.^dSame as footnote *r* of Table 1.^eValue not found in the literature.^fSame as footnote *f* of Table 4.^gSame as footnote *h* of Table 5.^hFrom BDE[(CH₂=CH)₂CH–H] = 316.3 (footnote *d* above) and $\Delta_f H^\circ[(CH_2=CH)_2CH_2] = 106.3 \pm 1.3$ (Ref. 20), $\Delta_f H^\circ[(CH_2=CH)_2C^\bullet H] = 204.6$ kJ mol^{−1}.ⁱSame as footnote *j* of Table 5.

and the calculation yields -138.9 kJ mol^{−1} by adding 20.9 to $\Delta_f H^\circ[C_6H_5CH_2CH_2CH_3]$ 8.3 for the RR'CHNH₂ function and subtracting 168.2 for the 2° alcohol RR'CHOH function.

For NH₂ connected to 3° carbon, there appear to be only two experimental values available. Both are accommodated accurately by $\Delta_f H^\circ[RR'R''CNH_2] = \Delta_f H^\circ[RR'R''CH] + 12.1$ kJ mol^{−1} and the relationship should be applicable to all such amines.

A plot of the four destabilizing constants of (17)–(20) versus the dipole contribution to BDE[R–NH₂] given by Pauling's $96.23 \times (\chi[R] - \chi[NH_2])^2$ yields a straight line with a correlation coefficient of 0.9996.

There are relatively few values of the enthalpies of formation of nitrogen-centered radicals. It appears that enthalpies of such radicals derived from primary amines can be estimated by $\Delta_f H^\circ[RNH^\bullet] = \Delta_f H^\circ[RNH_2] + 200$ kJ mol^{−1} when the nitrogen is not connected to an sp²- or sp-hybridized carbon. Three available examples are, $\Delta_f H^\circ[CH_3NH^\bullet] = \Delta_f H^\circ[CH_3NH_2] + 200 =$

$-23.4 + 200 = 176.7$ versus experimental 184.1 ± 8.2 ; $\Delta_f H^\circ[(CH_3)_3CNH^\bullet] = \Delta_f H^\circ[(CH_3)_3CNH_2] + 200 = -120.5 + 200 = 79.5$ versus experimental 95.4 ± 12.6 ; and $\Delta_f H^\circ[C_6H_5CH_2NH^\bullet] = \Delta_f H^\circ[C_6H_5CH_2NH_2] + 200 = 87.9 + 200 = 287.9$ versus experimental 288.3 ± 12.6 . Using the known $\Delta_f H^\circ$ values for ethylamine, propylamine, and isopropylamine and adding 200, we calculate for the corresponding $\Delta_f H^\circ[RNH^\bullet] = 152.7$, 131.8, and 116.3, respectively. These values lead to BDE[RNH–H] = 417.9 kJ mol^{−1} for all three, which is consistent with available experimental values of BDE[CH₃NH–H] = 425.1 ± 8.4 and BDE[C₆H₅CH₂NH–H] = 418.4. The results are also consistent with theoretical CBS-Q calculations that have obtained BDE[CH₃NH–H] = 413.4, BDE[CH₃CH₂NH–H] = 415.9 and BDE[CH₃CH₂CH₂NH–H] = 422.5 kJ mol^{−1}, with an expected uncertainty of about ±6.¹¹²

Other available values for nitrogen-centered radicals are $\Delta_f H^\circ[PhNH^\bullet] = 244.3 \pm 4.2$, leading to BDE[PhNH–H] = 375 ± 5 kJ mol^{−1}; $\Delta_f H^\circ[H_2NNH^\bullet] = 243.5$, leading to BDE[H₂NNH–H]

$= 366.1$ and $\text{BDE}[\text{H}_2\text{N}-\text{NH}_2] = 285.3 \text{ kJ mol}^{-1}$. CBS-QB3 calculations have given $\Delta_f H^\circ[\text{CH}_3\text{N}^+\text{NH}_2] = 202.9 \pm 7.5$, $\Delta_f H^\circ[\text{CH}_3\text{NHN}^+\text{H}] = 213.8 \pm 7.5$, $\text{BDE}[\text{CH}_3\text{N}(\text{NH}_2)-\text{H}] = 331$, and $\text{BDE}[\text{CH}_3\text{NHNH}-\text{H}] = 341 \text{ kJ mol}^{-1}$.¹¹³ 2,2-Diphenyl-1-picrylhydrazyl (2,4,6-tri-O₂N-C₆H₂-N⁺N(C₆H₅)₂ = DPPH) is a persistent free radical that has been used extensively, particularly for assaying total concentration of antioxidants in foods. The N-H bond dissociation enthalpy is quoted as $334.7 \text{ kJ mol}^{-1}$; density functional theory (DFT) calculations led to 341.4 ¹¹⁴ and 346 .¹¹⁵

In free-radical brominations of hydrocarbons by *N*-bromosuccinimide, the succinimidyl radical was suspected of being the hydrogen abstracting species. However, it has been established that, under the usual bromination conditions (nonpolar solvents), Br[•] is the abstracting radical.^{116,117} Compounds of the type RC(O)NH₂ have been reported to have quite strong N-H bonds: $\text{BDE}[\text{HC}(\text{O})\text{NH}-\text{H}] = 476 \text{ kJ mol}^{-1}$ and $\text{BDE}[\text{CH}_3\text{C}(\text{O})\text{NH}-\text{H}] = 469$,¹¹⁸ compared to $\text{BDE}[\text{CH}_3\text{NH}-\text{H}] = 425.6$. Evidently, in RC(O)N[•]H, the carbonyl function does not seem to stabilize the odd electron on the adjacent nitrogen.

Enthalpies of formation of compounds free of “special effects” can be obtained for many other functional groups from $\Delta_f H^\circ$ of the precursor hydrocarbon obtained by (4) plus a constant: ethers, aldehydes, ketones, carboxylic acids, esters, chlorides, nitriles, and amides.⁶⁹ The relationships can be used to calculate enthalpies of formation for compounds QH and obtain $\Delta_f H^\circ[\text{Q}^{\bullet}]$ if $\text{BDE}[\text{Q}-\text{H}]$ is known. Unpublished work from this laboratory for thiols indicates $\Delta_f H^\circ[\text{RSH}] = \Delta_f H^\circ[\text{RH}] + c_i$, where c_i depends on the nature of H: 52.3 for replacing H of methane, 38.1 for 1° H, 29.3 for 2° H, 25.5 for 3° H, and 29.7 for aromatic H.

4 RADICAL STABILIZATION ENERGIES AND SCALES

Knowledge of relative radical stabilities is fundamental to the design of radical reactions. All else being equal, more stable radicals should be easier to form than less stable ones. For example, in the well-studied unimolecular cleavage of alkoxy radicals, $\text{RR}'\text{R}''\text{CO}^{\bullet} \rightarrow \text{R}'\text{R}''\text{C}=\text{O} + \text{R}^{\bullet}$, generally the amounts of various radical products formed should reflect the relative radical stabilities

of the three R groups. The more stable radical should be the predominant radical product of cleavage.^{119,120} In radical additions to double bonds, the site of attack is generally the one that leads to the more stable radical product as in $\text{H}_3\text{C}^{\bullet} + \text{H}_2\text{C}=\text{CHPh} \rightarrow \text{CH}_3\text{CH}_2\text{C}^{\bullet}\text{HPh}$, rather than $\text{PhCH}(\text{CH}_3)\text{C}^{\bullet}\text{H}_2$, because the benzyl radical is more stable than a primary alkyl radical. In hydrogen abstraction by bromine atoms from isobutane, the hydrogen abstracted is the single one that leads to the formation of the more stable tertiary alkyl radical 98% of the time, rather than one of the other nine that lead to the formation of a primary radical. Excellent descriptions of the importance of radical stability and its role in synthesis and catalysis are available.^{121,122}

A perennial problem with the concept of relative radical stabilization energies has been the question “relative to what?” Common current practice is to use the C-H bond of methane as the reference standard. Accordingly, the radical stabilization energy of a species R[•] is defined as $\text{RSE} = \text{BDE}[\text{H}_3\text{C}-\text{H}] - \text{BDE}[\text{R}-\text{H}]$. This appears to be a logical definition: Cleavage of the C-H bond of methane to produce a methyl radical and a hydrogen atom requires $439.3 \text{ kJ mol}^{-1}$. Cleavage of the C-H bond of ethane to produce an ethyl radical and a hydrogen atom requires only 422.6. In both cases, a hydrogen atom is formed; hence it is easier to form an ethyl radical than a methyl radical by 24.9 kJ mol^{-1} , which is assumed to be a quantitative measure of the resonance stabilization energy of ethyl relative to methyl radicals. This argument has been presented in many textbooks for many years, but it has been shown to be embarrassingly illogical. The same argument can be applied to the cleavage of the C-F bonds of methyl fluoride and of ethyl fluoride. In both cases, a fluorine atom is formed, but $460.2 \text{ kJ mol}^{-1}$ is required to cleave the bond and form the methyl radical and 467.4 is required to form the ethyl radical. With the fluorides, it is easier to make methyl rather than ethyl radicals. Now the conclusion is that the ethyl radical is more stable! The fault in the argument presented is that it considers only the products and disregards the relative stabilities of the reactants. As Pauling has pointed out, dipoles strengthen bonds.¹²³ The C-F bond dipole in ethyl chloride is stronger than the C-F dipole in methyl chloride, because there is a greater electronegativity difference between ethyl and fluorine than between methyl and fluorine. The difference in dipole effect

makes the C–F bond of ethyl fluoride stronger. The C–F bond of *tert*-butyl fluoride is stronger than that of methyl fluoride by 35.6 kJ mol^{-1} . In using $\text{BDE}[\text{H}_3\text{C}-\text{H}]$ as a reference standard, one disregards potentially different effects of the C–H dipole in comparing $\text{H}_3\text{C}-\text{H}$ to various R–H.

The argument has been made that the C–H bond dipole is very weak and can be safely neglected. While it is true that various C–H bond dipole contributions to BDE constitute a relatively small percentage of the total BDE, the dipole effects are not negligibly small compared to the relative stabilization energies of carbon radicals versus methyl.¹²⁴ Pauling used $\text{BDE}[\text{H}_3\text{C}-\text{CH}_3] - \text{BDE}[\text{R}-\text{R}]$ to estimate the radical stabilization energy of the allyl and benzyl radicals relative to $\text{RSE}[\text{H}_3\text{C}^\bullet] = 0$, from $\text{BDE}[\text{CH}_2=\text{CHCH}_2-\text{CH}_2\text{CH}=\text{CH}_2]$ and $\text{BDE}[\text{PhCH}_2-\text{CH}_2\text{Ph}]$. This avoids complications from differing dipole effects of C–H bonds that would occur in comparing $\text{BDE}[\text{H}_3\text{C}-\text{H}]$ to $\text{BDE}[\text{R}-\text{H}]$.¹²⁵ Preferences for using the symmetrical option of $\text{BDE}[\text{R}-\text{R}]$ to establish relative radical stabilizations have been expressed by others in the past.¹²⁶ An extensive tabulation of radical stabilization values based on $\text{BDE}[\text{R}-\text{R}]$ is available.¹²⁷ Nevertheless, the use of $\text{RSE} = \text{BDE}[\text{H}_3\text{C}-\text{H}] - \text{BDE}[\text{R}-\text{H}]$ is still widespread.^{128,129} Estimating the extent to which a radical is stabilized in this way has the advantages of (i) simplicity, (ii) the fact that more C–H bond strengths have been measured than R–R, and (iii) the minimization of steric effects since hydrogen is the smallest substituent that can be attached to the radical.¹³⁰ In addition, the ordering of the stabilization of various radicals appears to be about the same for both options. Even though it was recognized that the use of $\text{BDE}[\text{R}-\text{R}]$ is better suited to quantifying substituent effects in radical centers, a justification that has been offered for continued use of C–H bond strengths is that they have the advantage of relating directly to the elementary process of transferring a hydrogen atom from one radical to another, the much studied hydrogen abstraction reaction.¹²¹

There are, however, two major problems with using $\text{BDE}[\text{R}-\text{H}]$ to quantify stabilization energies. The first is that anything called “radical stabilization energy” must be an inherent property of the radical.¹³⁰ It must be transferable with the radical to species other than the one from which it was derived. Such RSE values are

not transferable. For example, RSE values relative to $\text{BDE}[\text{H}_3\text{C}-\text{H}] = 376.6 \text{ kJ mol}^{-1}$ are $\text{RSE}[\text{H}_3\text{C}^\bullet] = 0.0$, $\text{RSE}[\text{CH}_3\text{C}^\bullet\text{H}_2] = 18.3 \pm 2$ and $\text{RSE}[\text{CH}_2=\text{CHC}^\bullet\text{H}_2] = 70.7 \pm 3$. Therefore, $\text{BDE}[\text{CH}_3-\text{CH}_2\text{CH}_3]$ should be equal to $\text{BDE}[\text{CH}_3-\text{CH}_3] - \text{RSE}[\text{H}_3\text{C}^\bullet] - \text{RSE}[\text{CH}_3\text{C}^\bullet\text{H}_2]$. Substituting these RSE values results in $\text{BDE}[\text{CH}_3-\text{CH}_2\text{CH}_3] = 376.6 - 0.0 - (18.3 \pm 2) = 358.3 \pm 2$; the experimental value of 370.1 ± 3 is significantly different. Also, $\text{BDE}[\text{CH}_3\text{CH}_2-\text{CH}_2\text{CH}=\text{CH}_2]$ should be equal to $\text{BDE}[\text{CH}_3-\text{CH}_3] - \text{RSE}[\text{CH}_3\text{C}^\bullet\text{H}_2] - \text{RSE}[\text{CH}_2=\text{CHC}^\bullet\text{H}_2] = 376.6 - (18.3 \pm 2) - (70.7 \pm 3) = 287.6 \pm 4$; the experimental value is 312.9 ± 10 . Clearly, such RSE values are not transferable to carbon–carbon bonds. The second problem is that, when dealing with radicals that are not carbon-centered, the reference bond is changed. For nitrogen-centered radicals, the reference bond becomes $\text{BDE}[\text{H}_2\text{N}-\text{H}]$.^{131,132} For oxygen-centered radicals, it is $\text{BDE}[\text{HO}-\text{H}]$, for sulfur-centered radicals $\text{HS}-\text{H}$, and so forth.¹²¹ It is not clear exactly how these different stability scales relate to each other. What has become clear is that, no matter what bond and species are chosen as the reference point for radical stabilization energies, arguments can and have been made in favor of some other, presumably superior choice.^{133,134}

The ideal situation is to have no particular reference compound and to have only one stability scale for all radicals. This is attainable, provided the focus is not on stability but on instability. An instability scale is established by defining the instability of any radical $\text{Q}^\bullet$ as $\text{DE}[\text{Q}^\bullet] = \frac{1}{2} \times \text{BDE}[\text{Q}-\text{Q}]$, where DE denotes destabilization energy. The zero of this scale simply corresponds to a hypothetical $\text{BDE}[\text{Q}-\text{Q}] = 0.0$.¹³⁵ Values of DE for many common groups are given in Table 7. To obtain $\text{BDE}[\text{CH}_3-\text{CH}_2\text{CH}_3]$, one simply adds $\text{DE}[\text{CH}_3]$ and $\text{DE}[\text{CH}_2\text{CH}_3]$. The result is $373.2 \text{ kJ mol}^{-1}$, which agrees with the experimental value of 370.1 ± 3 . For $\text{BDE}[\text{CH}_3\text{CH}_2-\text{CH}_2\text{CH}=\text{CH}_2]$, the result is 313.3 versus experimental 312.9 ± 10 . Simply adding the DE values in these two cases is successful because the electronegativity difference between these particular carbon radicals is very small and contributes little to the BDE. In the general case of an A–B bond, bond dissociation enthalpies are obtained from (21).

$$\text{BDE}[\text{A}-\text{B}] = \text{DE}[\text{A}] + \text{DE}[\text{B}] + 96.23(\chi_{\text{A}} - \chi_{\text{B}})^2 \quad (21)$$

Table 7 Destabilization energies of R (kJ mol⁻¹) and electronegativities for use with (21), where A and B are replaced by R' and R''.^a $BDE[R' - R''] = DE[R'] + DE[R''] + 96.23 \times (\chi[R'] - \chi[R''])^2$.

^aNot to be used when the A–B combination will result in steric hindrance or conjugation. Not to be used for groups –OR and –NR₂ connected to sp²- or sp-hybridized atoms (e.g., –C₆H₅, –CR=CR₂, –C≡CR, –NO₂, –BH₂).

^bConjugation-free value obtained from BDE[R–CH₃] and BDE[R–Cl].

^cStrain-free value obtained from BDE[R–CH₃] and BDE[R–OH].

This is Pauling's electronegativity equation,¹²⁵ where DE is the inherent bonding ability and χ is the electronegativity, which is a measure of the affinity of the atom or group for electrons. The value of χ was defined by Pauling to pertain to an atom or group in a stable molecule and in its normal oxidation state.

In the case of a group like *tert*-butyl, it is obvious that BDE[(CH₃)₃C–C(CH₃)₃] is not useful for obtaining inherent bonding ability because

of the known steric hindrance that weakens the central C–C bond. However, the inherent bonding ability of *tert*-butyl is obtainable from the known BDE[(CH₃)₃C–OH], BDE[(CH₃)₃C–Cl] or BDE[(CH₃)₃C–CH₃] and their combinations. Similarly, the central bond of 1,3-butadiene does not reflect the inherent bonding ability of vinyl because of the known strengthening of the central C–C bond by conjugation. The inherent bonding ability of vinyl is obtainable from vinyl compounds not subject to “special effects” of conjugation such as BDE[CH₂=CH–Cl], BDE[CH₂=CH–CH₃], and so on. The DE values of Table 7 are inherent properties of the species and are free from “special effects” that are present in A–A but not in A–B, or vice versa. Justification for the negative DE values of Table 7 has been provided.⁶⁹ An example of using the negative DE of O₂ in Table 7 is for the calculation of BDE[CH₂=CHCH₂–OO•] by (21) and the values for CH₂=CHC•H₂ and •OO• from Table 7: $BDE = 128.4 + (-98.2) + 96.23(2.489 - 3.225)^2 = 82.3$ versus 86.8 by a different calculation in Table 6, and 79.5 experimental. Not only does the negative DE work, but it also makes sense; there is no positive BDE[•OO–OO•] because O₄ does not exist. Two molecules of oxygen at covalent bond distances repel each other—negative BDE.

In addition to its utility in calculating BDE among many common groups, there are some important lessons lurking in Table 7. When thinking of radical reactivity, we tend to think that HO• is inherently very reactive. However, HO• is not even in the top half of Table 7. Methyl radical is more destabilized and, therefore, should be more reactive than hydroxyl. In fact, H₃C• is more reactive in abstracting halogen atoms. At 300 K, methyl radicals abstract chlorine from Cl₂ about 30 times faster than hydroxyl radicals do.¹³⁶ Our concept of reactivity is skewed by the fact that abstraction of hydrogen by hydroxyl or fluorine radicals form very strong bonds to the hydrogen. However, this has nothing to do with their inherent reactivity. Neither is very good at abstracting halogens. The high strength of the H–F and H–OH bonds has nothing to do with their inherent bonding ability. It is caused by the great difference in their respective electronegativities from that of hydrogen.

Pauling estimated the electronegativity of the elements by global fittings to the then known BDE values and noted that, unlike all other elements or

groups, the electronegativity of H is unique in its variability depending on what is bonded to it. There have been many published examples of failures of (4), but in every instance such reported failures are due to misapplication of the equation. Using (21) for species such as BDE[C–H] or BDE[Si–F] will, of course, lead to failure because the electronegativity of tetravalent carbon in a stable molecule such as methane will not be the same as its electronegativity in a species like CH. The carbon is not in its normal oxidation state and is not in a stable molecule. Similarly, the electronegativity of silicon in SiF will not be the same as that in SiF₄. Also, because bonds to hydrogen are among the most extensively and accurately known, (21) has been tested repeatedly against such bonds and has been found to give marginal results when using an average value for $\chi[\text{H}] = 2.2$, without regard to its known variability. However, in the last decade, it was demonstrated that (21) yields very accurate results with hundreds of common molecules with many different functionalities, hydrocarbons, alcohols, ethers, amines, halides, peroxides, silanes, thiols, sulfides, nitro compounds, and so on.¹²⁴ As a result, Pauling's equation is useful for estimating BDEs that are not available from experimental determinations and is as accurate as the highest level *ab initio* calculations available today. Unlike high-level *ab initio* theoretical calculations, (21) is equally as easy to apply to large complex molecules as to simple ones. Equation (21) does not take account of "special effects" (i)–(iv) as defined previously. Stabilization and destabilization constants of (8)–(20) were obtained without the use of Pauling's equation (21). Their excellent correlations with the electronegativity term of (21) are noteworthy.

5 HYDROGEN TRANSFER KINETICS

Attempts to predict reaction rates by some sort of *a priori* calculation go back to 1929, when London proposed the first quantum mechanically based equation for a reacting system.¹³⁷ For an atom transfer reaction $\text{A–B} + \text{C}^{\bullet} \rightarrow \text{A}^{\bullet} + \text{B–C}$, the energy of the reacting system was expressed in terms of the bonding and antibonding energies of three molecules: A–B, B–C, and A–C, at various combinations of bond distances on the way from reactants to the TS and to products. Resonance, then called the "overlap integral," was explicitly stated

to have been left unaccounted. This resonance stabilization energy would be due to the delocalization at the TS of the odd electron over the three-body system. There have been several attempts since that time to calculate reaction rates in terms of the components of the rate constant in the familiar Arrhenius equation $k = A \times \exp(-E_a/RT)$ or in Eyring's well-known formulation $k = (k_B T/h) \times \exp(-\Delta S^{\ddagger}/R) \times \exp(\Delta H^{\ddagger}/RT)$. For the most common type of atom abstractions, those of hydrogen transfer, the approximation can be made that $A \approx 10^{9\pm 1}$ for many reactions, and a successful calculation of the energy of activation would allow a decent estimate to be made of the rate constant and its temperature dependence. One of the early successes with a large variety of hydrogen abstractions was the BEBO method, despite a small number of failures.¹³⁸ The method calculated bonding energies at various distances using a bond energy–bond order correlation of Pauling and, significantly, a repulsive term between the terminal atoms A–C to calculate the energy hill from reactants to TS. Since that time, there have been many attempts to improve such calculations. Some are strictly empirical formulating parametric equations based on fitting to a large number of experimentally known energies of activation. One typical example is the work of Roberts and Steel.¹³⁹ A typical semiempirical approach is that of Formosinho *et al.*¹⁴⁰ With the advent of accurate quantum mechanical calculations there have been *ab initio* theoretical efforts. Examples are the study of the reaction of ethyl radical with ethylene¹⁴¹; hydrogen abstractions from alkanes by H and CH₃ via GA values based on CBS-Q calculations¹⁴²; the reactions of carbon radicals with thiols¹⁴³; CBS-QB3 calculations of hydrogen abstractions by alkyl radical from hydrocarbons¹⁴⁴; assessing various theoretical procedures for H abstraction by methyl radicals from benzene¹⁴⁵; and comparisons of various high levels of theory, testing for performance with hydrogen abstractions by variously substituted carbon radicals from methane and additions to variously substituted alkenes.¹⁴⁶ All these efforts however have not produced a basic, intuitive understanding of the factors involved, one that would allow us to guess whether a particular hydrogen abstraction would have a high or low energy of activation, without performing any calculations. One drawback of high-level *ab initio* calculations is that, even when they produce the correct result,

they do not necessarily provide an intuitive feeling or understanding of the physical process.

Typical of the current state of affairs is a recent account on “Understanding Hydrogen Atom Transfer.” It is pointed out that *tert*-butylperoxyl radicals abstract hydrogen from phenol about 10^5 times faster than from toluene, even though the O–H and C–H bonds broken are about the same strength, around 370 kJ mol^{-1} . It is pointed out that, evidently, bond strengths are not the only determinant of hydrogen-atom transfer reactivity. The reasons for the generally slower H transfer between carbon radicals compared to H transfer between oxygen radicals is described as “having been discussed, but no simple picture has emerged.”¹⁴⁷ The fact is that bond strengths are a major factor in controlling energy barriers to H-atom transfer, but not the bond strengths that were mentioned in the account or one would usually consider.

In a lecture of a chemical kinetics class some time ago, specifically when energies of activation were being presented, a student piped up saying “You have no idea what controls energies of activation. Do you?” Students in Brooklyn will do this sort of thing. The fact of the matter is that it is not that difficult to get a feeling of what is going on. For the reaction $\text{X-H} + \text{Y}^\bullet \rightarrow \text{X}^\bullet + \text{H-Y}$, London had it right in 1929. It is simple: you have three species XH, HY, and XY. You have bonding and you have antibonding; that is all, except for the resonance. The latter is no problem. We know that the resonance stabilization of the allyl radical is about 59 kJ mol^{-1} for delocalizing one electron over three atoms. Similar delocalization over three atoms in TSs probably produces about the same stabilization. At the TS, the strength of the bond being broken must equal the strength of the bond being made. H is going from the potential energy curve of X–H to the potential energy curve of H–Y. The TS is where the two curves cross, the hydrogen is at that point, and both curves have the same zero of energy. Hence, the partial bonding of $\text{X}^\bullet \cdots \text{H}$ must be equal to the partial bonding of $\text{H}^\bullet \cdots \text{Y}$. Bonding at various X–H bond lengths can be approximated by the Morse equation for $\text{X}^\bullet \cdots \text{H}$. The bond length of $\text{H}^\bullet \cdots \text{Y}$ required to match the bonding of $\text{X}^\bullet \cdots \text{H}$ is easily obtained from the H–Y Morse curve. At the TS, there are three canonical forms that can be written for the three electrons: $\text{X} \uparrow \downarrow \text{H} \uparrow \text{Y} \uparrow$, $\uparrow \text{X} \text{H} \downarrow \uparrow \text{Y}$, and $\text{X} \uparrow \text{H} \downarrow \text{Y} \uparrow$. Because H is simultaneously bonded to both X and Y, the three electrons

must be either $\uparrow \downarrow \uparrow$ or $\downarrow \uparrow \downarrow$. It follows that the electron spins on X and on Y must be parallel. This is antibonding and it is implicit in London’s original equation, even though he did not point it out.¹⁴⁸ There is an approximate equation proposed by Sato for calculating antibonding (the anti-Morse curve). At any equibonding combination of X–H and H–Y bond lengths, the Sato function can be evaluated and its repulsive term can be added to the bonding term. A zero-point energy correction can be applied to the total energy. The TS is at the combination of stretched bond distances that produces the lowest barrier between reactants and products. This is the calculated energy barrier, similar to the Arrhenius activation energy. The computer program that does all this requires the information needed for constructing the empirical bonding and antibonding curves: For X–H, H–Y, and X–Y: BDE, equilibrium bond length, IR stretching frequency, and masses of the directly bonded atoms. The program executes in less than 0.1 s and its results match well experimentally determined energy barriers for hundreds of hydrogen abstractions involving many types of X–H and of Y.⁵⁴ The details of the calculation are not important. The lesson learned is that mostly, but not exclusively, the energy of activation goes into overcoming the triplet repulsion between X and Y.¹

Returning to the reaction $\text{tert-BuOO}^\bullet + \text{H-OPh}$ versus $\text{H-CH}_2\text{Ph}$, it is not the strength of the bonds broken and made that controls the height of the barrier in this case. In this essentially thermoneutral reaction, it is the X–Y antibonding that must be overcome, the triplet repulsion. Antibonding energy is proportional to BDE. With (21) and values from Table 7, $\text{BDE}[\text{CH}_3\text{OO-OPh}] = 35.8 + 7.5 + 96.23(3.303 - 3.377)^2 = 43.8$ and $[\text{CH}_3\text{OO-CH}_2\text{Ph}] = 35.8 + 139.3 + 96.23(3.303 - 2.506)^2 = 236.2 \text{ kJ mol}^{-1}$. Antibonding at the TS is almost nonexistent for $\text{ROO}^\bullet + \text{H-OPh}$ and this is why phenols are such a good hydrogen donors to the autoxidation chain-propagating species $\text{ROO}^\bullet$. There is a simple picture.

Phenol is not a particularly good free-radical trap for other radicals. In abstraction by benzyl radicals from phenol, the antibonding species is $\text{PhCH}_2\text{-OPh}$, with $\text{BDE} = 219.7 \text{ kJ mol}^{-1}$. This reaction will not be nearly as fast as abstraction by $\text{ROO}^\bullet$. It must not be forgotten that phenols do not inhibit the polymerization of styrene. Walling polymerized styrene in *m*-cresol solvent!¹⁴⁹ While the

molecular weight of the polymer was of the order of 33 000 rather than the 150 000 obtained in the absence of phenolic solvents, it clearly demonstrated that phenols are not particularly good inhibitors of all free-radical chain reactions.

Good antioxidants are not only those that easily transfer a hydrogen atom to peroxy radicals. The product radical formed must not be able to combine with $\cdot\text{OO}\cdot$ and thus continue the chain reaction. 1,4-Cyclohexadiene has C–H bonds about as weak as the O–H bond of α -tocopherol, but is not an antioxidant because it reacts with $\cdot\text{OO}\cdot$ to form $\text{ROO}\cdot$ that continues the chain. Table 7 has the information required for calculating the strength of the bond that $\text{PhO}\cdot$ will make with $\cdot\text{OO}\cdot$. $\text{BDE}[\text{PhO}-\text{OO}\cdot] = 7.5 + (-98.2) + 96.23(3.376 - 3.225)^2 = -88.5 \text{ kJ mol}^{-1}$. Bond formation is endothermic and it does not occur. O_2 would react with the ring carbons of phenoxyl radical to make hydroperoxyl radicals that continue the chain, but those positions are all blocked in α -tocopherol and other manmade antioxidants.

The simple picture of looking at the molecule that is never present in hydrogen abstractions, the chimera X–Y antibonding species, explains many types of reactions in which a stronger O–H bond is attacked in preference to a weaker C–H bond. *tert*-BuO $\cdot$ radicals abstract the phenolic hydrogen of *p*-HOC₆H₄CH₂C₆H₄-*p*-OH rather than the benzylic hydrogens where the C–H bond is 25 kJ mol^{−1} weaker than O–H.¹⁵⁰ The antibonding species is *tert*-BuO–OR in the preferred abstraction, much weaker with less triplet repulsion than *tert*-BuO–CHAr for the shunned abstraction. The experimental activation energy for H abstraction from the N–H group of dimethylamine is smaller than abstraction from a C–H, even though the latter is the weaker bond. The reason for this is that the preferred abstraction has an O–N antibonding group, while the less favored abstraction has O–C. O–N bonds are weaker with less triplet repulsion than O–C bonds and generate smaller energy barriers.¹⁵¹ Abstraction by hydroxyl radicals from methylamine occurred only 37% of the time from one of the three C–H bonds and 63% from the N–H bond, even though the latter is 35 kJ mol^{−1} stronger (Table 1) and has a statistical disadvantage of 3:1.¹⁵² Even though this aspect was not fully addressed, it is clear that a major, if not the controlling, factor is the relative BDEs of the antibonding

species; O–N bonds being weaker than O–C bonds cause smaller triplet repulsion and lower barrier.

Triplet repulsion explains the often reported “compensation effect” that is observed in hydrogen abstractions that are not particularly exothermic, but proceed with very low energies of activation. The pre-exponential Arrhenius term that is related to entropic effects tends to drop rather precipitously compared to similar reactions with higher activation energies. Although this has been observed several times, there is no broad acceptance of any particular explanation for the effect. If the low energy of activation is caused by low triplet repulsion at the TS, as it is for reactions of peroxy radicals abstracting H from phenols, then one should expect exactly such an effect. The low repulsion allows the X and Y terminal groups to approach more closely for a tighter TS structure and, therefore, more unfavorable entropy of activation.

Very similar thermoneutral reactions with similar X–H, H–Y, and X–Y BDEs can show significantly different energies of activation. CH₃–H + $\cdot\text{CH}_3$ has $E_a \approx 60 \text{ kJ mol}^{-1}$ while H–H + $\cdot\text{H}$ has E_a less than 38. Their BDEs are about the same. Another lesson learned is that, everything else being equal, the reaction that has the higher IR frequency for X–Y has the lower E_a . This is so because high frequencies produce narrower potential energy curves. At a given distance, antibonding will be smaller when the curve is narrow. In comparing the reactions CH₃–H + $\cdot\text{CH}_3$ and CH₃–H + $\cdot\text{OC}(\text{CH}_3)_3$, the abstraction by *tert*-butoxyl radical has a much lower energy of activation even though the bonds involved are fairly similar in BDE. However, the IR stretching frequency of the antibonding species CH₃–OC(CH₃)₃ is much higher than that of CH₃–CH₃ and this produces lower antibonding at the same distance and lower E_a .⁵⁴

6 SUBSTITUENT EFFECTS ON BDE AND ON RATES OF ATOM ABSTRACTIONS

Effects on BDE of Y substituents are of different types. Effects of meta and para ring substituents on benzylic BDE[YC₆H₄CH₂–X] and effects on BDE[YCH₂–X].

Abstractions of benzylic H from substituted toluenes by various radicals have been studied

extensively. All such abstractions occur with negative slopes in Hammett plots. Electron-withdrawing substituents retard the rate of abstraction. Some older reports of positive Hammett slopes were found to have been caused by then unsuspected radical additions to the ring.¹⁵³ Conversely, rates of abstraction of benzylic halogen atoms are always enhanced by electron-withdrawing substituents. Polar effects in the TS were routinely used to explain these facts, but it is now established that benzylic bond dissociation enthalpies are affected by ring substituents. When the bond dipole is toward the ring, $\text{ArCH}_2 \leftarrow \text{H}$, electron-withdrawing substituents stabilize the molecule, increasing the benzylic BDE, which results in slower rates of abstraction. That this is a BDE effect present in the parent molecule is shown by the dependence of $^{13}\text{C}-\text{H}$ coupling constants on the electron-donating or withdrawing ability of Y in the NMR of substituted toluenes, the magnitude of the coupling constant being proportional to the percent of s character of the bond and thus its strength.¹⁵⁴ The same trend of the effect of Y on reaction rates is also followed by quasi-benzylic bonds such as those of $\text{ArO} \leftarrow \text{H}$ and $\text{ArNH} \leftarrow \text{H}$, that have bond dipoles in the same direction. When the benzyl-X dipole is away from the ring, as in $\text{YC}_6\text{H}_4\text{CH}_2 \rightarrow \text{halogen}$, electron-withdrawing substituents destabilize the molecule and weaken the benzylic bond, which results in faster rates of halogen abstraction irrespective of the abstracting radical. This is an effect present in the parent molecules and is a net thermodynamic effect on the enthalpy of reaction, not an evanescent TS effect.^{155,156} In considering factors affecting in opposite ways the rates of abstraction of hydrogens versus halogens, the relative stabilization of the benzyl radicals formed is irrelevant because benzylic atom abstraction from $p\text{-O}_2\text{NC}_6\text{H}_4\text{CH}_2\text{-H}$ or from $p\text{-O}_2\text{NC}_6\text{H}_4\text{CH}_2\text{-Cl}$ produces the same radical.

For non-benzylic bonds, the most extensive work available consists of theoretical calculations at the level of G3(MP2)-RAD for a group of 64 YCH_2 radicals and their bonds to H, Cl, CH_3 , and the symmetrical $\text{YCH}_2\text{-CH}_2\text{Y}$; for the latter, there is no effect of bond dipoles on BDE.³¹ The most strengthened BDEs in the symmetrical compounds were those caused by the powerfully electron-withdrawing substituents $\text{Y} = \text{CH}_3\text{SO}_2$ and CF_3 . Electron-donating Y's cause a decrease in such BDEs. The range of BDE for the 64

Y is a substantial 112 kJ mol^{-1} . Some values of BDE in the upper and lower parts of this range are as follows: $\text{CH}_3\text{SO}_2\text{CH}_2\text{-CH}_2\text{SO}_2\text{CH}_3$, 403.4; $\text{CF}_3\text{CH}_2\text{-CH}_2\text{CF}_3$, 402.0; $\text{HOCH}_2\text{-CH}_2\text{OH}$, 361.8; $\text{HSCH}_2\text{-CH}_2\text{SH}$, 321.8; $\text{H}_2\text{NCH}_2\text{-CH}_2\text{NH}_2$, 318.2; $\text{CH}_3\text{NHCH}_2\text{-CH}_2\text{NHCH}_3$, 313.1; and $(\text{CH}_3)_2\text{NCH}_2\text{-CH}_2\text{N}(\text{CH}_3)_2$, 291.3. For comparison, $\text{BDE}[\text{CH}_3\text{CH}_2\text{-CH}_2\text{CH}_3] = 366.8$ and $\text{BDE}[\text{C}_6\text{H}_5\text{CH}_2\text{-CH}_2\text{C}_6\text{H}_5] = 277.0$. From the above evidence, one may infer that $(\text{CH}_3)_2\text{NC}^*\text{H}_2$ is more stable than $\text{CH}_3\text{SO}_2\text{C}^*\text{H}_2$ because it takes less energy to form it by cleaving the symmetrical bond. However, the same calculation showed that $\text{BDE}[(\text{CH}_3)_2\text{NCH}_2\text{-Cl}]$ is stronger than $\text{BDE}[\text{CH}_3\text{SO}_2\text{CH}_2\text{-Cl}]$ by 7.3 kJ mol^{-1} , not weaker as would have been expected from the above inference. This is because the substituent does not only affect the inherent bonding ability of the carbon radical or its stability/instability, but it also affects its electronegativity: $\chi[(\text{CH}_3)_2\text{NC}^*\text{H}_2] = 2.28$ and $\chi[\text{CH}_3\text{SO}_2\text{C}^*\text{H}_2] = 2.80$; from Table 7, $\chi[\text{Cl}^*] = 3.174$. As a result, the C-Cl bond dipole in $(\text{CH}_3)_2\text{NCH}_2\text{-Cl}$ contributes 76.9 kJ mol^{-1} to the BDE, while the C-Cl dipole in $\text{CH}_3\text{SO}_2\text{CH}_2\text{-Cl}$ contributes only 13.5. The interplay of both DE and of electronegativity must be considered as is done with the DE and χ values of Table 7.

7 CONCLUSION

A wealth of thermodynamic information, both experimental and theoretical, has become available. This has helped increase dramatically our understanding of radical reactions and has facilitated their use in many areas of chemistry, biology, and technology. Both experimental and theoretical contributions have been described in this article. Their impact on our understanding radical reactivities has been significant, but much still remains unclear and differences of opinion in rationalizing the known facts still exist.

END NOTES

^a See Ref. 36. The authors report high level theoretical calculations yielding $356.1 \text{ kJ mol}^{-1}$ for the enthalpy of formation of the ground state triplet ethylidene.

^b. See Ref. 37. Values calculated by a group additivity scheme fashioned on the basis of CBS-QB3 theoretical calculations. The reported GAV values are reduced here by 6 kJ mol^{-1} because the calculated values are invariably too high by an average of 6 kJ mol^{-1} when compared to available experimental values.

^c. See Ref. 43. The authors report $\Delta_f H^\circ$ [1-ethylcyclohexanol] = $\Delta_f H^\circ$ [cyclohexanol] – 28.6 = $(-290 \pm 8) - 28.6 = -321.8 \pm 8 \text{ kJ mol}^{-1}$.

Radical Kinetics and Clocks

Martin Newcomb

Department of Chemistry, University of Illinois at Chicago, Chicago, IL, USA

1 INTRODUCTION

The interest in organic radical chemistry increased tremendously in recent decades as synthetic methods for using radicals in fine chemical synthesis were refined and the occurrence of radical intermediates in productive biological processes became better understood. Both for synthetic planning with radicals and for mechanistic understanding of processes involving radical transients, the rate constants of radical reactions are critically important. Most radicals are highly reactive transients that couple with one another with diffusion-controlled rates, but most productive radical reactions require that the radicals react with closed-shell molecules with velocities that minimize the extent of radical–radical reactions. In order to achieve that condition in a preparative reaction, one must control velocities by the concentrations of reagents, and synthetic planning is greatly simplified when the rate constants for the radical reactions are available. The concept of applying radical kinetics for synthetic planning is well accepted by all contemporary organic chemists, and many radical rate constants were determined by organic chemists for that specific objective.

Radical rate constants can be measured directly in physical chemistry laboratories equipped with fast detection methods, typically by UV–visible spectroscopy, and pulse irradiation methods such as laser flash photolysis (LFP) or pulse radiolysis for generation of radicals. Alternatively, indirect kinetic methods can be accomplished in most organic chemistry preparative laboratories. In an indirect

method, products from competitive reactions are quantified after work-up by a spectroscopic or chromatographic technique, and the ratio of products, concentrations of reagents, and the known rate constant for one of the competing reactions, the so-called basis reaction, is used to determine the rate constant for the reaction of interest. This simple approach requires no special instrumentation, and it has been widely applied, often by chemists who wish to use the information in designing new conversions, and most of the radical kinetic data used in synthetic planning has come from indirect studies.

Radical reaction rate constants are an integral part of the description of radical reactions, and they are contained in most of the sections of this encyclopedia for the specific radicals of interest in each article. A comprehensive listing of radical kinetics is beyond the scope of this article, but absolute rate constants are listed here for representative values for some common reactions to demonstrate trends. The major focus of this article is on the application of competition kinetic studies that can be applied for a wide range of radical reactions and a cataloging of various types of “radical clocks” that can be used in competition studies.

When a radical process used as a basis reaction in indirect studies is a first-order rearrangement, the reaction is commonly termed a *radical clock*, an appellation used by Griller and Ingold in a seminal review published in 1980.¹ That report established guidelines for competition kinetic studies and can be credited with generally informing the organic community of the availability and utility of the methods. Radical clocks provide an obvious advantage

in experimental design because the basis reaction is self-contained, and one does not need to control concentrations of a trapping reagent. Nonetheless, the range of kinetics for which any given radical clock can be applied is limited because one cannot alter the rate constant of the clock reaction. Therefore, a collection of radical clocks with a wide range of rate constants is desired for studies of new reactions with various reactivities. In practice, such a repertoire of radical clocks exists for alkyl radicals,² but clocks for carbon-centered radicals with stabilizing groups and for heteroatom-centered radicals are less well established. In this article, radical kinetics and indirect kinetic methods are described with an emphasis on radical clocks. Direct kinetic studies are discussed in **Analysis of Radicals by EPR and Structures and Reactivity of Radicals Followed by Magnetic Resonance**.

2 CHAIN AND NONCHAIN RADICAL REACTIONS

2.1 Examples of Chain and Nonchain Radical Reactions

Productive radical methods can involve either chain reactions or nonchain reactions, which are described briefly here for reference in the kinetic discussions that follow. Most chemists are familiar with chain reaction applications, which are the most common. Nonchain radical reactions are less familiar, but they can be very useful for fine chemical synthesis and highly controlled radical polymerizations.

A radical chain reaction sequence is composed of three parts, initiation, propagation, and termination, as exemplified in the tin hydride reaction of an alkyl bromide shown in Figure 1. Radicals are formed in the initiation reactions, typically by thermolysis or photolysis of an initiator (see **Overview of**

Radical Initiation). The initiation sequence can be a single reaction that gives radicals that enter into a subsequent propagation reaction or a sequence of reactions as shown in Figure 1. The productive steps in the chain sequence are the propagation reactions. In each individual propagation reaction, the product radical is a reactant radical for another propagation step. The propagation sequence can be simple, involving only one or two elementary reactions, or it can be complex with many competing reactions. The termination reactions involve radical–radical reactions, either couplings or disproportionations, that give closed-shell products. In principle, a variety of radical–radical termination reactions could be occurring in a chain sequence, but that is seldom the case. Because many chain termination reactions occur at diffusion control, the major termination pathway will be radical–radical reactions between the most abundant radical at steady state, which is controlled by the relative rate constants of the elementary propagation steps. For example, in the chain sequence in Figure 1, the $\text{Bu}_3\text{Sn}^\bullet$ radical reacts with RBr with a second-order rate constant that is about 100 times larger than that for the reaction of radical $\text{R}^\bullet$ with Bu_3SnH . An absolute condition of the chain sequence is that the two propagation reactions have the same velocity, and, in the case where the concentrations of alkyl halide and tin hydride are equal, this requires that the $\text{R}^\bullet$ concentration at steady state is 100 times as great as the $\text{Bu}_3\text{Sn}^\bullet$ concentration. Therefore, if all radical–radical reactions occur at diffusion control, then 99% of the termination events will involve reactions of two $\text{R}^\bullet$ radicals.

Nonchain radical reactions also can be applied productively for synthesis. The hallmark of a non-chain sequence is that one of the radical intermediates is persistent under the reaction conditions, a condition that arises because self-termination of that radical is slow or reversible. For example,

Figure 1 Tin hydride reduction of an alkyl bromide. Elementary steps in the radical chain reduction of an alkyl bromide with tin hydride.

Figure 2 The Barton reaction. Photolysis of the nitrite ester gives an alkoxy radical and the NO radical, which is persistent. Internal hydrogen atom transfer of the alkoxy radical gives the carbon-centered radical that is trapped by NO to give the nitroso compound. Rearrangement of the nitroso compound to an oxime is a nonradical reaction.

nitroxyl radicals lacking β -hydrogen atoms such as the 2,2,6,6-tetramethylpiperidine-*N*-oxyl (TEMPO) radical have small equilibrium constants for dimerization, and the $\cdot\text{NO}$ radical is stable with respect to coupling. The persistent radical is reactive with other radicals, however, and when it accumulates to a relatively high concentration, it captures all other radicals in cross-termination reactions because of its high concentration. The general phenomenon where all radicals cross-couple without multiple propagation steps is termed the *persistent radical effect* or the *Ingold–Fischer effect* for the authors who initially described it succinctly (see **Nitroxides in Synthetic Radical Chemistry and Fundamentals of Controlled/Living Radical Polymerization**).^{3,4}

The Barton reaction,⁵ illustrated in Figure 2, is a nonchain radical reaction that involves the $\cdot\text{NO}$ radical. In this reaction, photolysis of a nitrite ester gives the $\cdot\text{NO}$ radical and an alkoxy radical, which can recombine in a nonproductive step. The alkoxy radical can abstract a hydrogen atom from a neighboring carbon atom to give an alkyl radical, and the alkyl radical formed in this process will react with the $\cdot\text{NO}$ radical in a termination reaction to give a nitroso compound that rearranges to an oxime in a nonradical process.

2.2 Kinetics of Radical Chain Reactions

Chain reactions have a unique set of rate expressions, and an understanding of radical chain reaction

kinetics can be useful in the design of efficient conversions. The key points in a chain reaction are that (i) each propagation step in the chain sequence must have the same velocity and that (ii) under steady-state conditions that are obtained in a chain sequence, the velocity of the initiation sequence is equal to the velocity of the termination sequence. Because of these equalities, a series of steady-state assumptions can be made that result in the rate law for the chain reaction in terms of a few key rate constants for elementary reactions. Importantly, the rate constant for the slow step in the chain reaction, termed the *rate-controlling step*, is the only elementary propagation rate constant that appears in the rate law. For the radical chain reduction of an alkyl bromide with tin hydride shown in Figure 1, an alkyl radical reacts with tin hydride with a rate constant of about $2 \times 10^6 \text{ M}^{-1} \text{ s}^{-1}$ at room temperature,⁶ and the $\text{Bu}_3\text{Sn}\cdot$ radical reacts with an alkyl bromide with a rate constant that is about 100 times greater.⁷ If the reaction is initiated by thermal decomposition to azo-*bis*-isobutyronitrile (AIBN), then the total rate law for the chain reaction is given in (1). In (1), k_{init} is the first-order rate constant for the initiator homolysis step,⁸ f is the fraction of initiator radicals that escape from the solvent cage, k_{SnH} is the second-order rate constant for the rate-controlling reaction of alkyl radical with tin hydride, and k_{term} is the second-order rate constant for termination, often equal to 25% of the diffusion control rate constant due to the spin statistical requirement that radicals have proper

spin orientations to form singlet products, which occurs in 25% of the encounters of two odd-electron species.⁹ The rate law will be similar for photochemical initiation, but the k_{init} and f terms are replaced by the photon flux and quantum yield of the photolysis and, if the solution is not opaque, the absorbance.

$$\frac{d[\text{RX}]}{dt} = \frac{k_{\text{init}} f [\text{AIBN}]^{1/2} k_{\text{SnH}} [\text{Bu}_3\text{SnH}]}{2k_{\text{term}}^{1/2}} \quad (1)$$

With general knowledge of the rate constants for the elementary processes, one can predict the velocity of chain reaction. Consider the reduction of RBr with Bu_3SnH using AIBN initiation in refluxing benzene with the following concentrations: $[\text{RBr}]_0 = [\text{Bu}_3\text{SnH}]_0 = 0.2 \text{ M}$; $[\text{AIBN}]_0 = 0.005 \text{ M}$. The rate constants at 80°C are $k_{\text{init}} = 2 \times 10^{-4} \text{ s}^{-1}$ for AIBN homolysis, $k_{\text{SnH}} = 6.4 \times 10^6 \text{ M}^{-1} \text{ s}^{-1}$, $k_{\text{term}} = 1 \times 10^{10} \text{ s}^{-1}$, and $f \approx 0.5$. Under these conditions, the velocity of the chain reaction is about $3 \times 10^{-4} \text{ M s}^{-1}$, and the reaction would be complete in about 15 minutes. Substituting the slower reacting $(\text{Me}_3\text{Si})_3\text{SiH}$ ($k_{\text{SiH}} = 1.3 \times 10^6 \text{ M}^{-1} \text{ s}^{-1}$ at 80°C) for the tin hydride would increase the reaction time to about 1 hour.

The importance of the rate-controlling reaction is readily understood by example. If one replaced RBr with RI as a radical precursor in the tin hydride example, the rate of reaction of $\text{Bu}_3\text{Sn}\cdot$ with RI would be increased to the diffusion-control limit, but the reaction of $\text{R}\cdot$ with Bu_3SnH would be unchanged. Therefore, the transient concentration of $\text{Bu}_3\text{Sn}\cdot$ would be reduced, but the overall velocity of the process would not be affected provided that the initiation reaction was unchanged. Alternatively, replacing the tin hydride with tris(trimethylsilyl)silane would result in a reduced rate for the overall reaction as noted above. In addition, the overall reaction also would be slowed if RBr was replaced with RCl as the radical precursor. In this case, the rate constant for the reaction of $\text{Bu}_3\text{Sn}\cdot$ with RCl is appreciably smaller than that for the reaction of the stannyl radical with RBr and, in fact, even smaller than that for the reaction of $\text{R}\cdot$ with tin hydride.⁷ The rate law for the overall reaction (1) would now contain the rate constant for the reaction of the stannyl radical with the alkyl chloride, and the velocity of the reaction would be reduced if other experimental details were unchanged.

2.3 Radical Chain Initiation Kinetics

In many conversions, radical chain reactions are initiated thermally by decomposition of an added initiator. For reactions conducted at elevated temperatures, Walling reported the following temperatures that gave 1-hour half-lives for decomposition of commercial or synthesized radical initiators (see **Overview of Radical Initiation**)⁸: di-*tert*-butyl peroxyoxalate, 45°C ; di-*tert*-butyl hyponitrite, 55°C ; AIBN, 81°C ; benzoyl peroxide, 91°C ; *tert*-butyl peroxybenzoate, 125°C ; and di-*tert*-butyl peroxide, 150°C . As a general rule, these temperatures can be considered to be typical reaction temperatures for the use of the particular initiator or a closely related initiator. A variety of thermal initiators exist, but it is noteworthy that Barton's PTOC (pyridine-2-thioneoxycarbonyl) ester radical precursors (see below for an example) decompose thermally in refluxing solvents such as tetrahydrofuran (THF) or toluene.¹⁰ Barton's PTOC esters also decompose when irradiated with visible light, which provides a convenient method for radical chain initiation at reduced temperatures.

A relatively new method of thermal initiation involves addition of a small amount of Et_3B to a reaction mixture that has not been degassed thoroughly.¹¹ The borane reacts with oxygen, apparently to generate ethyl radicals. The kinetics of this reaction are not available, but the reaction is known to be efficient at low temperatures, and this is an attractive method for initiation of radical reactions when one wishes to maintain low reaction temperatures to achieve selectivity in the conversions.

3 COMPETITION KINETICS AND RADICAL CLOCKS

3.1 Overview of Competition Kinetics

Although sophisticated instrumentation is needed for measuring radical kinetics due to the short lifetimes and small concentrations of radicals in typical reactions, kinetic studies can be accomplished in most wet chemistry laboratories without any special instrumentation by the use of competition experiments. The concept of the study is that a reaction with a known rate constant competes with

Figure 3 Reactions in a competition kinetic study. The 5-hexenyl radical cyclization competes with trapping by reagent XY, and the rate constant for the trapping reaction can be determined from the ratio of acyclic to cyclic products, the concentration of XY, and the known rate constant for cyclization.

the reaction with the unknown rate constant, and the unknown rate constant can be calculated from the product ratio obtained after the reaction, the concentrations of reagents employed, and the known rate constant. An example of a competition kinetic study is shown in Figure 3. In this sequence, the radical precursor, 6-bromo-1-hexene, reacts with Y[•] to give the 5-hexenyl radical, which is a “radical clock.” The clock cyclizes to the cyclopentylmethyl radical with a known rate constant (k_c), and the rate constant of interest is that for the reaction of trapping agent XY with the primary radical (k_{XY}). Because the cyclization reaction in this example is effectively irreversible, the rate constant for trapping the cyclic radical is not important. The ratio

of products is determined after the reaction, and the rate constant k_{XY} is calculated from that ratio, the concentration of trapping agent XY, and the known cyclization rate constant k_c .

3.2 Kinetic Expressions in Competition Kinetics

In a competition kinetic study, the products formed in the competing reaction are quantified, and the rate constant for the reaction of interest is determined from this product ratio, the concentrations of reagents, and a known rate constant for the basis reaction. If a unimolecular radical reaction (i.e., a radical clock, see below) is employed, the reaction is a first-order process by definition. From a practical perspective, it is most convenient to use large excesses of reagents in bimolecular processes such that pseudo-first-order conditions are maintained. Nonetheless, true second-order kinetics with changing concentrations of reagents can be handled with the correct kinetic expression. Table 1 contains the kinetic expressions that apply to some of the more common experimental designs.

The precision necessary for a rate constant is a function of the desired application. When high precision is needed, one should study the reaction with a variety of concentrations of the radical trapping agent to prevent errors due to reversibility of the clock reaction. Many first-order radical reactions are effectively irreversible, but the following example

Table 1 Kinetic expressions for competition kinetic experiments.^a

Type of study	Kinetic expression
First-order (k_1) vs pseudo-first-order (k_2)	$k_1/k_2 = ([R^1X]/[R^2X])([XY]_m)$
First-order (k_1) vs second-order (k_2)	$k_1/k_2(\ln([XY]_i + k_1/k_2) - \ln([XY]_f + k_1/k_2)) = [Sub]_i ([R^2X]/[R^1X]) (1 + ([R^2X]/[R^1X]))^{-1}$
Pseudo-first-order (k_1) vs pseudo-first-order (k_2)	$k_1/k_2 = ([RX^1]/[RX^2]) ([X^2Y]_m/[X^1Y]_m)$
Second-order (k_1) vs second-order (k_2)	$k_1/k_2 = (\ln([X^1Y]_i)/([X^1Y]_i - [RX^1]))/(\ln([X^2Y]_i)/([X^2Y]_i - [RX^2]))$
Reversible first-order(k_1) vs pseudo-first-order (k_2)	$(k_1/k_2)(k_2/(k_{-1} + k_2[XY]_m)) = [R^1X]/[R^2X]$

^aIn these expressions, the trapping agent is XY, which reacts by transfer of X to the radical. The subscript in $[XY]_i$ indicates initial concentration, that in $[XY]_f$ indicates final concentration, and that in $[XY]_m$ indicates average concentration. The rate constants k_x in the kinetic expressions are shown in the type of study column in parentheses. Products with superscripts 1 and 2 are those formed in the first and second reaction, respectively, in the type of study column.

illustrates the potential problem of reversibility. Ring opening of the cyclopropylcarbinyl radical (see Section 4) is a well-recognized fast radical reaction, and this reaction has been used as a competition reaction in many indirect kinetic studies. The equilibrium constant for the cyclopropylcarbinyl radical at 20 °C strongly favors the ring-opened product ($K \approx 10\,000$ at room temperature).¹² In the phenyl-substituted analog, the cyclopropylbenzyl radical, the ring opening of the cyclopropyl group is reasonably fast ($k = 6 \times 10^4 \text{ s}^{-1}$ at 20 °C¹²), but the ring-opened product is disfavored ($K = 0.012$ at room temperature).^{12,13} Nonetheless, the benzylic radical can still be used as a competing reaction in a competition study with appropriate caution.

A determination of a second-order rate constant at a single concentration of reagent would not provide a unique rate constant unless the trapping reaction of the ring-opened radical was fast relative to the back-reaction. However, this problem is avoided if one conducts a series of reactions at a variety of concentrations. Figure 4 illustrates the situation for the

case where radical $A^\bullet$ equilibrates with $B^\bullet$, and both radicals react with trapping agent XY to give products AX and BX. In this case, the ratio of products will change with the concentration of the trapping agent as shown in the idealized plot in Figure 4. The rate constants in this situation are described by (6). Note that the rate constants for the back-reaction and trapping reaction of the rearranged radical are not needed to obtain the rate constant for the trapping reaction of radical $A^\bullet$ with XY.

$$\frac{AX}{BX} = \frac{k_{X1}k_{R2}}{k_{X2}k_{R1}} + \frac{k_{X1}}{k_{R1}}[X-Y]_m \quad (6)$$

Figure 4 Results from hypothetical competition kinetics experiments for a radical clock reacting in the presence of bimolecular trapping reagent XY used in excess where the rearrangement has $k_{R1} = 1 \text{ s}^{-1}$, and the trapping reaction has $k_{X1} = 0.5 \text{ M}^{-1} \text{ s}^{-1}$. When the rearrangement is effectively irreversible, $k_{R2} \approx 0 \text{ s}^{-1}$, then the plot with an intercept at the origin (open symbols) is obtained. If the clock rearrangement is reversible with rate constant $k_{R2} = 3 \text{ s}^{-1}$ and the trapping rate constant for the rearranged radical is $k_{X2} = 1 \text{ M}^{-1} \text{ s}^{-1}$, then the plot with the solid symbols is obtained. The slopes of the lines give k_{X1}/k_{R1} , which is the same for both cases. If the reversible clock was studied only at 0.4 M concentration of XY with the assumption that the reaction was not reversible, however, then the dashed line would be obtained, and the derived trapping reaction rate constant would be in error by nearly a factor of 2.

3.3 Basis Reactions for Radical Clocks

Any kinetic method could be used to calibrate a radical clock, and several clocks were calibrated by direct EPR or UV-visible spectroscopy with flash lamp or LFP methods to generate the radicals. However, many carbon radical clocks were calibrated indirectly with a limited number of trapping agents. The two most common methods, the tin hydride method and the PTOC-thiol method, can be used for a wide range of radicals and are illustrated in this section.

3.3.1 The Tin Hydride Method

In the tin hydride method, the radical precursor is a halogen or pseudo-halogen and tributyltin hydride or another group 14 hydride is used as the trapping agent (see **Tin Hydrides and Functional Group Transformations**). Group 14 metal hydrides are the most completely calibrated family of radical trapping agents, and rate constants for reactions of Bu_3SnH , Ph_3SnH , $(\text{Me}_3\text{Si})_3\text{SiH}$, and Et_3SiH with many carbon-, nitrogen-, and oxygen-centered radicals are known.¹⁴ The most widely used reagent for calibration has been Bu_3SnH , which reacts with

alkyl radicals with rate constants that were determined using LFP methods in the early 1980s.^{6,15} These directly measured rate constants were combined with previously determined relative rate constants to give absolute rate constants for clock reactions. For example, cyclization of the 5-hexenyl radical in competition with tin hydride trapping was quite well studied by Walling in the late 1960s and early 1970s,¹⁶ and combination of the relative rate constants for those processes with the absolute tin hydride values gave absolute rate constants for cyclization of the 5-hexenyl radical and launched contemporary radical clock chemistry.

The experimental design for a tin hydride competition study is illustrated in Figure 3. The radical precursor typically is an alkyl halide or pseudohalide, although other radical precursors can be used. Tin hydride or other group 14 hydride is used in excess so that pseudo-first-order reaction conditions are maintained. In early studies, reactions were usually initiated by thermolysis of AIBN or a similar initiator at temperatures between 70 and 110 °C. In more recent studies, radical initiation by reaction of triethylborane with oxygen at room temperature or reduced temperatures has been common.

As in synthetic applications of radical chemistry, a competition kinetic study requires an efficient chain reaction sequence. For group 14 hydrides, tin and germanium hydrides react fast enough with alkyl radicals to maintain chain conditions, but

trialkylsilanes such as Et₃SiH do not. The substituted (Me₃Si)₃SiH (see **Silanes as Reducing Reagents in Radical Chemistry**) reacts considerably faster with alkyl radicals than common silanes, and this reagent is an excellent hydrogen atom trapping agent for alkyl radicals. For trapping more reactive radicals such as aryl, vinyl, and oxyl radicals, Et₃SiH is adequately reactive to propagate chain reactions.

In regard to the radical precursor limitations, the group 14 trialkylmetal radical must react efficiently with the precursor. Silyl radicals are highly reactive with various halides or pseudohalides, but stannyl radicals react only sluggishly with alkyl chlorides. For aryl and vinyl radical generation, iodides are recommended as the radical precursors. There is no direct counterpart for heteroatom radical generation in the tin hydride protocol.

3.3.2 The PTOC thiol method

The PTOC thiol method is a kinetic adaptation that employs Barton's PTOC esters (anhydrides of a carboxylic acid and the thiohydroxamic acid *N*-hydroxypyridine-2-thione) as radical precursors (Figure 5). In this method, the PTOC ester reacts to give an acyloxyl radical, and decarboxylation of the acyloxyl radical gives the target radical. The target radical can react with a wide range of

Figure 5 Fundamental reactions in the PTOC thiol method. The radical precursor is a mixed anhydride of a carboxylic acid and the thiohydroxamic acid, *N*-hydroxypyridine-2-thione, termed a PTOC ester. The PTOC ester decomposes thermally or photochemically with visible light irradiation to give an acyloxyl radical that rapidly decarboxylates to give the radical of interest. Reaction of that radical with a thiol competes with a rearrangement (not shown). The thiyl radical reacts with another PTOC ester molecule to give the disulfide product and another acyloxyl radical.

hydrogen atom donors including the highly reactive thiophenol and benzeneselenol (selenophenol), and the radicals formed from the hydrogen atom transfer step react with another molecule of PTOC ester in a propagation step.

The PTOC thiol method has two significant advantages over the tin hydride method as well as two significant disadvantages. Owing to the high reactivity of the thione group in the PTOC ester and related radical precursors, a wide range of propagating radicals can be used including any group 14 atom centered radical and the group 16 thio- and seleno-centered radicals. This feature opens the kinetic method to the use of highly reactive H-atom transfer agents, such as benzeneselenol. In addition, the PTOC ester methodology has been extended to the production of nitrogen- and oxygen-centered radicals, which were not readily available in the tin hydride method. On the negative side, the high reactivity of the thione group results in relatively efficient reactions of the precursors with carbon-centered radicals,¹⁷ and it is difficult to “time” a slow carbon radical reaction by this method because the radical precursor will intercept the carbon-centered radicals in a “self-trapping” reaction. The other disadvantage of the method is due to the requisite intermediacy of the acyloxyl radicals; acyloxyl radical precursors to aryl and vinyl radicals will not decarboxylate rapidly enough to avoid some trapping of these radicals by many H-atom trapping agents.

4 RADICAL CLOCKS

Competition kinetic methods commonly employ radical clocks,¹ which are calibrated unimolecular radical reactions. The clock reactions are cyclizations, fragmentations including ring openings, or migrations that involve initial cyclizations and subsequent ring openings. The primary advantage of a radical clock is that the competition reaction is self-contained and additional reagents are not necessary, but this property works to limit the useful dynamic range of a clock.

4.1 Carbon Radical Clocks

Alkyl radical clocks are the most numerous, with calibrated clocks ranging in rate constants at room

temperature from 300 s^{-1} to greater than $3 \times 10^{11}\text{ s}^{-1}$. Table 2 contains a representative selection of alkyl radical clocks.^{6,15,16,18–30} This collection is intended to show the breadth of calibrated clocks employing examples that are not especially difficult to prepare and whose products are reasonably easy to characterize. The Arrhenius functions should be considered operational equations that predict rate constants reasonably well but do not necessarily provide highly accurate entropies and enthalpies of activation. Most of the kinetic values were determined from competition kinetic studies using the rate constant for the reaction of Bu_3SnH as the basis reaction, which illustrates the fundamental importance of the tin hydride rate constants.^{6,14}

Substituted alkyl radical clocks are well represented in the context of 5-exo cyclizations with rate constants in the range of 1×10^5 to $1 \times 10^8\text{ s}^{-1}$ at room temperature (Table 3).^{6,16,31–35} A noteworthy point of these rate constants is the similarity of the values for both series of monosubstituted (i.e., secondary) radicals. For the tertiary radicals, however, significant reductions in rate constants were observed for the planar conjugated radicals (carboethoxy and cyano substituents), and this effect is most likely due to steric compression in obtaining the transition state for cyclization as opposed to stabilization due to the substituent.³⁴

Some benzyl radical clocks are available. A problem with these clocks is that the high stability of the benzyl radical limits the number of reactions possible. For example, the 5-exo cyclization shown in Figure 6 is slow,²¹ and the ring opening of the cyclopropylbenzyl radical, while reasonably fast, is reversible with the cyclic product favored.^{12,13} For the (2-phenylcyclopropyl)benzyl radical, the phenyl

groups at the radical center and incipient radical center cancel one another, and the rate constant for ring opening is similar to that for ring opening of the unsubstituted parent, the cyclopropylcarbonyl

radical.³⁶ It is noteworthy that all three of the benzyl radical reactions shown in Figure 6 are about 3 orders of magnitude slower than the reactions of the corresponding primary alkyl radicals.

^aRate constants at 20 °C in units of s^{−1}.

Aryl and vinyl radical clocks are not well represented. In early studies, diacylperoxide precursors to the phenyl and 2,2-dimethylvinyl radical were irradiated with laser light with the intention of producing the corresponding acyloxyl radical that could decarboxylate. Rate constants for reactions of tin hydride were determined in these studies,¹⁵ but it was later learned that the initially formed acyloxyl radicals did not decarboxylate completely before reaction with the tin hydride.

In more recent studies, a rate constant for the reaction of an aryl radical with tin hydride at room temperature was determined to be $k = 7.8 \times 10^8 \text{ M}^{-1} \text{ s}^{-1}$.³⁷ If this value is used with previous competition kinetic results, the rate constants at 25 °C for cyclization of the aryl radicals shown in Figure 7 are 5×10^8 and $8 \times 10^9 \text{ s}^{-1}$ at room temperature.¹⁵ The relative rate constant

**Figure 7** Examples of aryl and vinyl radical clocks. The rate constants are for reactions at room temperature.

for cyclization of vinyl radical in Figure 7 and trapping by tin hydride is 0.9 M at 80 °C.³⁸ If one assumes that the rate constant for tin hydride

Figure 8 Examples of fluorocarbon radical clocks. The rate constants are for reactions at 30 °C.

reaction with the vinyl radical is equal to that for reaction with the aryl radical, then the rate constant for cyclization of the vinyl radical clock in Figure 7 is $7 \times 10^8 \text{ s}^{-1}$; the assumption is based on the fact that vinyl and alkene C–H bond energies are quite similar.

Products from fluorocarbon radical reactions are of high commercial interest owing to the stability of the polymers and the low refractive index of fluorocarbons. Cyclizations of a series of fluorine-containing 5-hexenyl radicals³⁹ and other fluorine-containing radical cyclizations⁴⁰ have been studied. Two examples are shown in Figure 8.³⁹

4.2 Nitrogen Radical Clocks

A number of nitrogen-centered radical clocks have been calibrated, most by direct LFP. Some early nitrogen radical clock calibrations were attempted by the kinetic EPR method,⁴¹ but the method is difficult to interpret when no comparative values are available. The advantage of the direct LFP approach is that absolute kinetic values can be obtained with good accuracy and precision in many cases, but the disadvantage is that the clocks might not be appropriate for a wide range of studies. In order to detect the products in LFP studies, many of the clocks were designed to give UV–visible detectable benzylic or diphenylalkyl radicals. In indirect studies with these clocks, these relatively stable product radicals might not react efficiently with trapping agents in follow-up reactions, which can result in high radical concentrations that interfere with an indirect kinetic study. Nonetheless, with appropriate control reactions, these clocks can be used in indirect kinetic studies when the trapping agents are

Figure 9 Nitrogen radical clocks that react by cyclizations. The rate constants for 5-exo cyclizations at room temperature are listed.

highly reactive as in reactions of tin hydrides or thiols.

Figure 9 shows a number nitrogen-centered radical clocks involving 5-exo cyclizations, and Figure 10 shows nitrogen radical clocks that react by fragmentations. In both figures, appropriate carbon radical clocks are provided that permit comparisons with carbon radical analogs. Aminyl radicals are relatively low reactivity species in addition to alkenes,⁴² but fragmentations that produce a relatively stable imine π -bond are fast.^{42,43} Protonated dialkylaminium radical cations have long been known to be highly reactive,⁴⁴ and Lewis acid complexed aminyl radicals lie between the extremes of the neutral and protonated forms.⁴⁵ Amidyl radicals are much more reactive species than α -carbonyl carbon radicals,⁴⁶ but iminyl radicals are much less reactive than the carbon analog vinyl radicals.⁴⁷ In a predictable manner, phenyl substitution to give the nitrogen equivalents of benzyl radicals results in apparent low reactivity in a cyclopropane-substituted aniline radical cation⁴⁸ and in a variety of anilidyl radicals.⁴⁹

Figure 10 Comparisons of nitrogen radical fragmentations to carbon radical reactions. The rate constants are for reactions at room temperature.

4.3 Oxygen Radical Clocks

Oxygen-centered radicals are highly reactive species in comparison to carbon-centered radicals. The archetypal oxygen radical clock reaction is fragmentation of the *tert*-butoxyl radical to give acetone and a methyl radical, which has been studied for half a century.⁵⁰ Relative rate constants for competing fragmentation and reaction of the oxyl radical with solvent were reported long ago,⁵¹ and precise absolute rate constants were later determined by LFP methods.⁵² Most of the calibrated oxygen radical clocks are fragmentations similar to the *tert*-butoxyl radical reaction,^{53–55} but cyclizations,⁵⁶ intramolecular hydrogen abstraction,⁵⁷ and rearrangements⁵⁸ have also been calibrated.

Figure 11 shows examples of oxyl radical clocks. One noteworthy point is that oxygen radical kinetics is sensitive to solvent polarity effects; for example, the rate constant for fragmentation of the *tert*-butoxyl radical in water is more than 100 times greater than that for fragmentation in CCl_4 .⁵² Another important point is that an oxyl radical ring opening can be reversible, as seen in the cyclopentanoxyl radical,⁵⁵ although the carbon-centered radical product is favored thermodynamically.

4.4 Acyl Radical Clocks

Fragmentations of acyl radicals give alkyl radicals and carbon monoxide, and these decarbonylation reactions are reversible when conducted at high CO pressure. Several kinetic studies were conducted, and a number of results were collected in an overview published in 1987.⁵⁹ Some examples of acyl radical clocks are shown in Figure 12.^{60–64} The kinetics of these reactions was obtained over a wide temperature range and should be among the more accurate values available.

5 KINETIC TABLES

Radical reaction rate constants are presented in many of the articles in this encyclopedia in conjunction with the other details of the chemistry of the radicals. In this section, some of the more commonly encountered second-order rate constants are collected for convenient reference. These include rate constants for hydrogen atom transfer reactions from the more common radical reducing agents and addition reactions of carbon-centered radicals to various alkenes.

Figure 11 Examples of oxygen-centered radical clocks. The rate constants in units of s^{-1} are for reactions at approximately room temperature.

5.1 Hydrogen Atom Transfer Kinetics

Table 4 contains rate constants for the reactions of some of the more commonly employed hydrogen atom transfer reactions. Hydrogen atom transfer reactions of group 14 hydrides and group 16 hydrides are the best characterized radical reactions kinetically, and Table 4 lists values for the most commonly employed reagents.

The most commonly employed radical reducing agent has been tributyltin hydride, Bu_3SnH , which has been used extensively for half a century and is the species referred to as *tin hydride*. Triphenyltin hydride, Ph_3SnH , is more reactive than Bu_3SnH .

Tributylgermanium hydride is somewhat less reactive than Bu_3SnH ; it can be used in many radical reactions, but it seldom has been. Simple trialkylsilanes such as Et_3SiH react too slowly with alkyl radicals to propagate a chain reaction sequence, but the activated silane *tris(trimethylsilyl)silane*, $(\text{CH}_3\text{Si})_3\text{SiH}$, reacts fast enough with carbon radicals to be useful (see **Silanes as Reducing Reagents in Radical Chemistry**). A contemporary review of group 14 hydride reagents and their radical reactions contains the most comprehensive collection of kinetics for these reagents.¹⁴

For comparisons with the other group 14 hydrides, the rate constants for reactions of the

silane hydrogen of Et₃SiH with *tert*-butoxyl radical and a simple alkyl radical at room temperature are 4.6×10^6 and $3.2 \times 10^2 \text{ M}^{-1} \text{ s}^{-1}$, respectively.^{14,69,70} Note that the methylene hydrogens in Et₃SiH also are transferred to radicals, resulting in somewhat larger overall rate constants than those quoted here. Also for comparison purposes, Bu₃GeH reacts at room temperature with *tert*-butoxyl and alkyl radicals with rate constants of 9.2×10^7 and $9.5 \times 10^4 \text{ M}^{-1} \text{ s}^{-1}$, respectively.^{14,70–72} Triphenyltin hydride has been well studied and the rate constants for reactions

with many radicals have been collected¹⁴; Ph₃SnH reacts somewhat faster than Bu₃SnH.

Group 16 hydrides are well-known hydrogen atom donors. Phenols have long been used as inhibitors for spoilage, but thiols are more commonly applied in synthetic applications, and benzeneselenol is a highly reactive trapping agent. Thiols are highly reactive hydrogen atom transfer agents with nucleophilic radicals such as alkyl radicals. Many thiols are readily available, and *tert*-butylthiol rate constants are relatively well

studied. Thiophenol is highly reactive, and benzeneselenol reacts at close to diffusion control at room temperature.^{21,25,26,29,30,33,65–67}

The group 16 hydrides are limited to some extent in their applications in that the thiyl and selenyl radicals will not abstract halogen atoms from an alkyl halide radical precursor, although they can be used with the PTOC class of radical precursors developed by Barton and coworkers.¹⁰ Nonetheless, it is possible to use a group 16 hydride as fast radical trapping agents with an alkyl halide radical precursor if a group 14 hydride is added as a sacrificial reductant, a method termed *polarity reversal catalysis*.⁷³ For example, Et₃SiH and *t*-BuSH can be used in combination to reduce an alkyl halide. The thiol reacts rapidly with the alkyl radical, the thiyl radical thus formed will not react with the alkyl halide but does react with the silane to give a silyl radical, and the silyl radical then reacts efficiently with the alkyl halide. This method was also applied with (Me₃Si)₃SiH as sacrificial reductant in a calibration of rate constants for a collection of thiols reacting with alkyl and acyl radicals.⁶⁸ In a similar manner, one can generate PhSeH *in situ* by reaction of PhSeSePh with Bu₃SnH and use the combination of the diselenide and tin hydride as an efficient reducing agent with alkyl halide radical precursors.⁷⁴ In passing, one should note that chalcogenide (or pseudohalide) radical precursors such as RSPH or RSePh can be contaminated with impurities of dichalconides PhSSPh and PhSeSePh, respectively, which are reduced by Bu₃SnH to give the highly reactive hydrides PhSH and PhSeH; thus, it is possible to generate a highly reactive radical reducing agent unintentionally when pseudohalide radical precursors are employed.⁷⁴

A new aspect of hydrogen atom transfer to alkyl radicals is evolving at the time of this writing. Owing to the toxicity of tin-containing compounds, chemists have sought “tin-free” alternatives for many years. For example, Derek Barton noted that the family of PTOC ester radical precursors he and his coworkers developed in the 1980s¹⁰ were aimed in part at removing the need for tin hydride in radical applications in synthesis. More recently, there has been progress in using water and simple alcohols as hydrogen atom donors toward radicals. The strong OH bond in water is significantly weakened by complexation with Lewis acids, and water and alcohols complexed

with boron species have been shown to react with carbon radicals.^{75,76} A kinetic study of the reactions of triethylborane-complexed water and methanol found the rate constants for reactions on the order of $1 \times 10^4 \text{ M}^{-1} \text{ s}^{-1}$ at room temperature,⁷⁷ but an unusual entropic term was found, indicating that an equilibration preceded the rate-determining hydrogen atom transfer step. Recently, Renaud and coworkers (private communication from Dr. G. Povie for results from G. Poive, M. Marzorati, P. Bigler, and P. Renaud) found that the equilibrium constant for binding water and Et₃B was quite small at room temperature, a result consistent with the unusual entropic term obtained in the kinetic studies. This observation suggests that the measured rate constant for hydrogen atom transfer reactions of Et₃B complexed water and alcohols might be only a small fraction of the true rate constant, which might be nearly as great as that for tin hydride. One is encouraged to refer to contemporary studies reported after this review was written for recent progress in this area.

5.2 Additions to Alkenes

The rates of reactions of radicals with alkenes provides insight into the reactivities of the radicals and the substrates. A large collection of background data was accumulated by the late Hans Fischer and coworkers who studied reactions of radicals that can be classified as nucleophilic (α -oxygen substituted),⁷⁸ electrophilic (α -ester substituted),⁷⁹ and mixed (ambiphilic, alkyl)⁸⁰ reactivity. Table 5 contains collections of data that show the reactivities of various radicals with different alkenes. The table includes data from Dolbier and coworkers for reactions of the perfluoropropyl radical.⁸¹

A relative complete collection of rate constants for reactions of alkyl radicals with other unsaturated substrates is collected in Table 6.^{82–87} This data is presented in terms of relative rate constants because it was derived from both inter- and intramolecular reactions. It can be used as a predictor of radical reactivity for a given substrate in reactions with alkyl radicals and possibly other nucleophilic radicals, but one must be cautious about using this table for electrophilic radicals such as alkoxyl or perfluoroalkyl radicals.

5.3 Radical Fragmentation Reactions

Radical fragmentations display kinetic effects that are similar to those observed in radical additions. The stability of the incipient radical center is the dominant feature in the kinetics for a series of fragmentations. Table 7 contains rate constants for a series of cyclopropylcarbinyl ring opening reactions that are collected from various sources.^{12,28,29,33,88–91} The entropic terms are quite similar for these reactions, and the enthalpic terms provide the major effects on the

kinetics. For the series of radical center-substituted cyclopropylcarbinyls, the rate constants are similar except in the case of the highly stabilized benzyl radical. On the other hand, the rate constants for the series of cyclopropylcarbinyl radicals that give substituted product radicals vary widely.

6 CONCLUSION

This overview of radical kinetics is intended to provide a foundation for designing indirect kinetic studies and the application of radical clocks in addition to background kinetic information on some of the more common radical reactions. Kinetic information is an integral part of the description of any radical reaction, and much kinetic information is presented in this encyclopedia in the specific articles describing various types of radicals. Radical kinetic studies have been a focus of interest for many years, and kinetic results fill volumes. Nonetheless, one should appreciate that most radical-based synthetic methods were developed without complete knowledge of absolute rate constants, which highlights the importance of a qualitative understanding of radical kinetics and reactivities.

1 INTRODUCTION

In most cases, radicals are rather short-lived and appear at low steady-state concentrations. One way of detecting them is to provide an inert environment, which precludes their quenching. Accordingly, radicals are often generated in rigorously dried solvents and the exclusion of air is substantial. Moreover, reaction partners, being able to convert radicals to diamagnetic species (e.g., by recombination reactions or electron transfer), have to be excluded. With such precautions, radicals can exist for several minutes or even hours and can be preferentially investigated by standard electron paramagnetic resonance (EPR) techniques. Such reaction conditions, however, cannot be met in all cases and, moreover “real time” detection and a kinetic analysis at a short timescale are highly desirable (Scheme 1).

Time-resolved EPR (TR-EPR) also denoted as CIDEF (chemically induced dynamic electron polarization) and CIDNP (chemically induced dynamic nuclear polarization) spectroscopy ideally meet these requirements. Both techniques rely on a trigger, which starts the generation of radicals (e.g., a laser or rapid mixing), and take advantage of magnetic-field effects (which are explained below).

This article presents an elementary introduction to the principles underlying the detection of radicals at a nanosecond–microsecond timescale and introduces a couple of representative examples for the application of TR-EPR (CIDEF) and CIDNP. The common feature of these techniques is that they take advantage of “radical-pair” effects, which are active at applied magnetic field and lead to a substantial enhancement of EPR and nuclear magnetic resonance (NMR) lines, thereby making it possible to detect short-lived radicals generated at rather low concentrations (in the micromolar range).

The aim of this article is to introduce the principles underlying these techniques (see **Analysis of Radicals by EPR**) and present typical examples. The basic chemical reactions are presented in more detail and the applications of these fundamental reactivity patterns are sketched to illustrate the scope of CIDNP and CIDEF.

2 CIDNP

2.1 The Effects of Radical Pairs

During the last few decades, NMR spectroscopy has been established as a powerful analytical method in physics, materials science, chemistry, medicine, and biochemistry known for its high content of

Scheme 1 Radicals at short timescales and their detection by CIDNP and CIDEP.

information. Even highly complicated secondary, tertiary, and even quaternary structures become accessible by the application of advanced techniques. One major drawback is its comparatively low sensitivity resulting from the small energy gaps between the involved spin states, which leads to the necessity of developing high-field instruments, thereby limiting the application of NMR in many fields.

However, samples, in which fast free-radical reactions are taking place, often show substantially (up to three orders of magnitude) enhanced NMR signals. Moreover, such NMR spectra show perturbed intensities and phases for lines belonging to reaction products formed via paramagnetic intermediates. This phenomenon of nuclear hyperpolarization is called *chemically induced dynamic nuclear polarization (CIDNP)*.

How can nuclear spins be involved in free-radical chemistry? The answer is based on the interaction between electron and nuclear spins and the total spin conservation in chemical reactions together with their spin selectivity. It is simple and easy: a chemical reaction is allowed only if the total spin of reactants coincides with the spin of the product (generally closed-shell singlet). Chemical reactions produce diamagnetic species from intermediate

radical pairs (RPs, Scheme 2). An RP has four states: one singlet state with antiparallel orientation of electron spins and three triplet states with their parallel mutual orientation.

Usually, only the singlet RP can form a product, while the triplet can not. Transition between triplet and singlet states is induced by the local magnetic field via *hyperfine interaction (HFI) of the unpaired electron with nuclei* and by magnetic interaction with the external static magnetic field. These phenomena are reflected in the NMR signals of the products formed via RPs at short timescales. Thus, CIDNP provides an indirect way for detecting elusive short-lived radicals, to determine their structure and reaction mechanisms. Several aspects of CIDNP spectroscopy were reviewed recently.¹

2.2 CIDNP—The Scope

The combination of pulsed Fourier transform-NMR (FT-NMR) and nanosecond pulsed lasers made a breakthrough in developing the method of time-resolved CIDNP (TR-CIDNP) detection that opens the way to monitor chemical reactions of radicals on the microsecond timescale by NMR. Here,

Scheme 2 The formation of radical pairs and their spin-selected follow-up reactions.

we first present an overview of the quantitative treatment of CIDNP to demonstrate the high potential and ability of the TR-CIDNP technique as analytical and informative tool in free-radical chemistry. The first part provides the reader with some phenomenological background and helps in understanding the TR-CIDNP technique and observations described thereafter. The experimental technique is a subject of the second section. Herein, the experimental setup for the acquisition of time-resolved spectra is depicted, applications of TR-CIDNP methods to the analysis of fast reactions and characterization of short-lived reaction intermediates are discussed, and the proportionality of CIDNP intensity to hyperfine coupling constants (HFCCs) is introduced. Experimental examples include photoinduced reactions of amino acids, nucleotides, peptides, and proteins. CIDNP as a tool to study intra- and intermolecular electron-transfer reactions is also considered in detail. The application of CIDNP to probe accessibility of the amino acid residues in proteins and protein folding is reviewed. The final part presents examples of determination of g -factors of radicals and electronic exchange interaction in biradicals from CIDNP field dependence.

2.3 CIDNP: Phenomenological Description

The term *chemically induced dynamic nuclear polarization* (CIDNP) is used for hyperpolarization

observed in the NMR spectra of reaction products resulting from a radical reaction that exhibit anomalous intensities and phases in their spectral lines. The CIDNP phenomenon illustrates the importance of the spin degrees of freedom in the chemistry of RPs. The origin of CIDNP is the spin-selective recombination of RPs, resulting from spin conservation during chemical reactions. CIDNP effects arise when the electronic triplet–singlet conversion of an RP is the bottleneck for the reaction. The leading mechanisms of its formation are well understood^{2–5} and shall be reviewed only briefly. Several tutorials,^{6–8} reviews,^{1,9,10} and monographs^{11–14} have appeared on the theory and CIDNP applications to organic chemistry.

Since its first report by Bargon *et al.*,¹⁵ CIDNP has been studied in detail and turned into a widely used tool for the investigation of chemical reactions with radical intermediates. Kaptein and Oosterhoff first developed the theory of the so-called radical pair mechanism (RPM),^{2,3} which is valid for CIDNP and for electron polarization (CIDEP; see Section 6). This mechanism depends on the existence of a stage of interaction between two radicals in a “cage,” when they constitute an RP (Scheme 2). The “cage” is, in principle, a time regime at which an efficient reaction between two radicals forming the pair occurs. In this region, the radicals react only within the RP, whereas the probability of their reaction with other radicals is negligible.

Two radicals constituting the RP diffuse with respect to each other; a reaction between them takes

Figure 1 (a) Potential energy of a radical pair in a magnetic field as a function of interrational distance r . (b) Precession of electron spin vectors $\mathbf{S}_1$ and $\mathbf{S}_2$ of triplet-born radical pairs with α nuclear spin projection (upper row) and β nuclear spin projection (lower row) viewed in a frame rotating with $\mathbf{S}_2$. The recombination from singlet state is permitted, leading to enhanced absorption in the NMR spectrum of product.

place only at their direct contact. While caged, there is little mixing of the spin states because of the large electronic exchange energy, that is, the large singlet–triplet splitting in the spin-correlated pair at close distance. In addition, at high magnetic field, the energy levels of a triplet RP are split by Zeeman interaction into three sublevels: T_+ , T_0 , T_- (Figure 1). The magnitude of this splitting equals $g\mu_B B$, where g is the electron g -factor, μ_B is the Bohr magneton, and B is the magnetic-field strength. However, the exchange interaction, J , decreases exponentially with distance so that once the radicals are separated by the solvent molecules,

J becomes negligible and the energy difference between the S and T_0 spin states becomes small. In this case, the spin multiplicity of the RP can change under the influence of Zeeman and HFI as shown in Figure 1a. The electron spin state of the two radicals initially forming the RPs starts oscillating between triplet and singlet multiplicity because of their different Larmor frequencies, which depend on the electron g -factors of the two radicals and HFI. As a consequence of HFI, when the partner radicals in the spin-correlated RP re-encounter, they have different degrees of electronic singlet and triplet character depending on their nuclear spin states.

However, the lifetime of the RP is short compared to the oscillation frequency and, thus, only the beginning of the oscillations is seen. Consequently, the rate of multiplicity mixing is proportional to the difference in the Larmor precession frequencies, which is different for nuclear spin states (α and β) of the radicals (Figure 1b). For a positive HFI constant and a g -factor higher for the first spin S_1 than for the second S_2 , the Larmor frequency is higher for the RP with the nuclear spin oriented along the field (α -projection). For zero J , the rate of multiplicity mixing for RPs with α -projection is proportional to difference in g -factors and HFI constant, A , and equal to

$$\Delta_{\alpha,\beta}\omega = \left| \frac{\Delta\delta\mu_B B}{\hbar} \pm \frac{1}{2}A \right| \quad (1)$$

where A is the HFI constant. With the assumption that the reaction product formed at a re-encounter is a diamagnetic molecule in its singlet state, the probability of formation is proportional to the singlet character of the spin-correlated pair. Thus, the recombination product will be enriched in α nuclear spin states and depleted in β states (Figure 1b).

For RP at high magnetic field, (1) is extended readily to include as many nuclei as desired. Let the first radical have N magnetic nuclei with the HFCCs a_i and the second radical N' nuclei with the HFCCs b_j . Then the rate of singlet–triplet conversion ω for the certain nuclear spin state $\{M_1, \dots, M_N; M_1, \dots, M_{N'}\}$ is given by the expression¹⁶

$$\omega(M_1, \dots, M_N; M_1, \dots, M_{N'}) = \frac{1}{2}(g_1 - g_2)\mu_B B_0 + \frac{1}{2} \sum_{i=1}^N a_i M_i - \frac{1}{2} \sum_{j=1}^{N'} b_j M_j \quad (2)$$

Here, $\{M_i, M_j\}$ is the set of the z -projections of the nuclear spins in the selected spin state.

A simple analysis of CIDNP spectra detected at high field can be obtained by the empirically developed Kaptein's rules,¹⁷ which allow to predict the sign of the polarization (absorption or emission). For the net effect, the sign can be determined by four decisive parameters, according to the equation

$$\Gamma_i = (\mu)(\varepsilon)(\Delta g)(A_i) \quad (3)$$

where μ denotes the initial electron multiplicity of the RP at its formation (+ for triplet, – for singlet), ε the type of reaction leading to the observed products (+ for cage product, – for escaped products), $\Delta g = g_1 - g_2$ the sign of difference in g -factors of the two radicals (g_1 is the g -factor of the radical with nucleus under observation), and A_i the sign of the HFI constant. The sign product of these four parameters determines whether the sign, Γ_i , of the polarization for nucleus i indicates absorption (+) or emission (–).

The relative line intensities in the “geminate CIDNP” detected at high field can be calculated in the frame of Adrian's model.¹⁶

In fact, if an RP contains more than one magnetic nucleus, the above-described mechanism can give rise to two types of CIDNP effects: net and multiplet ones. In the case of two nuclei, there is a difference in the rate of electron multiplicity mixing for parallel and antiparallel mutual alignment of the two nuclear spins. The net effect occurs in the case of $\Delta g \neq 0$ as shown in Figure 1b. If $\Delta g = 0$, there can be no net polarization in any product but there can be a mixture of emissive and enhanced absorptive polarization—multiplet effect. This effect can be seen only if spins are scalar coupled in the diamagnetic product.

Here, we consider only the net CIDNP effect describing the net alignment of individual spins along the magnetic-field axis, and do not discuss more subtle effects such as the multiplet CIDNP effect that represents mutual ordering of spins. For the multiplet effect of two nuclei, there is the Kaptein's rule¹⁷ as well. The multiplet effects of higher orders can be revealed by their characteristic dependences on the detection flip angle.¹⁸ For high magnetic field of modern NMR spectrometers used for CIDNP detection, the term $\Delta g\mu_B B$ is not negligible in comparison with HFCCs; therefore, multiplet effects are usually weakly pronounced. Here, no multiplet CIDNP effect is further discussed.

Importantly, the above-mentioned effects are typically produced at a (sub) nanosecond timescale. However, the relaxation of the non-Boltzmann populated nuclear states is substantially slower, between hundreds of microseconds to seconds. This is the reason, why radical-pair-based reactions can be readily detected via the analysis of the reaction products with (essentially) standard NMR instruments.

2.4 Time-Resolved CIDNP

2.4.1 CIDNP Kinetics

CIDNP is a time-dependent effect. Nuclear polarization is formed in short-lived RPs and stored during relaxation times in diamagnetic reaction products, where it can be detected by NMR. Under continuous radical generation, only time-averaged or steady-state CIDNP spectra are detectable. In such conditions, CIDNP effects originating from primary RPs on nanosecond timescale cannot be discriminated from the radical reactions on microsecond timescale. Moreover, apparent polarization is heavily influenced by nuclear relaxation of the product. For photochemical reactions, submicrosecond time resolution in photo-CIDNP detection is achievable by the application of flash photolysis and by detection of polarization by FT-NMR at various delay times after the photolysis flashes.^{6,19–21} Although RPs can be formed in different ways, here only laser-induced photoreactions are discussed.

A liquid solution containing two types of molecules is considered, a dye (D) and a quencher (Q). For simplicity, the quencher molecule is assumed to have a single magnetic nucleus with spin 1/2 while the other molecule does not have any magnetic nuclei with HFI. Under light irradiation, the dye molecule absorbs a photon and is excited into a higher singlet state. After internal conversion followed by intersystem crossing (ISC) due to spin–orbit interactions, it reaches its lowest triplet state (Figure 2). The triplet formation in a molecule is usually fast ($\ll 1$ ns) compared to the laser pulse duration (5–15 ns). The next step is quenching of the triplet excited dye (3D) by the quencher molecule

(Q). This process strongly depends on the nature of the reactants and under the assumption that bimolecular reactions take place usually via electron (e) or, for example, hydrogen atom (H $\cdot$) transfer from Q to D or vice versa. Depending on the structure of the starting molecule and the quenching mechanism, the radicals formed can be charged or neutral. Another important factor influencing the quenching reaction is the nature of the solvent.

Since the total spin multiplicity does not change in the quenching process, the primary “geminate pair” is generated in a well-defined spin state (spin-correlated radical pair (SCRPs) denoted by an over bar). In the case considered, the RP is born in its triplet state (Figure 2). Subsequently, the RP can react to give geminate diamagnetic products or the radical partners can leave the “cage” by diffusing apart. The probability that the components of such a separated geminate pair re-encounter is finite, but falls off with time, and in low-viscosity solvents it becomes negligible after $\sim 10^{-7}$ s.

Let us assume that the RP is terminated by back e $^-$ or (H $\cdot$) transfer and can proceed only from an SCRPs with the same multiplicity as the subsequent ground state, which usually has singlet multiplicity. The rate of multiplicity mixing is proportional to the difference in the Larmor precession frequencies, which is different for nuclear spin states (α and β) of the radicals. For a positive HFI constant and a g -factor higher for Q $\cdot$ than for D $\cdot$, the Larmor frequency is higher for the RP with the nuclear spin oriented along the field (α -projection, denoted by “ $\uparrow$ ” in Figure 2). With the assumption that the reaction product formed at a re-encounter is a diamagnetic species in its singlet state, the probability of formation is proportional to the singlet character of the spin-correlated pair. Thus, the

Figure 2 Radical pair mechanism of CIDNP formation in a low-viscosity solution at high magnetic field. Here, SCRPs are denoted by a bar. For details see the text.

geminate products will be enriched in α nuclear spin states, $Q\uparrow$, and depleted in β states, $Q\downarrow$ (Figure 2). This process termed *spin sorting* leads to nuclear spin polarization in the geminate products and to an equally large polarization of opposite sign in the remaining radicals. The spin-sorting process in typical organic radicals with HFCCs of 15–60 MHz takes no more than 10 ns, and geminate product formation stops after 100 ns. The number of radicals that react in the geminate stage is usually small, whereas most of them diffuse into the bulk. Escaped radicals can re-encounter and form escape products with opposite to geminate polarization (Scheme 2, Figure 2).

After the geminate stage, the polarization formation in RPs in the bulk, so-called F-pairs, continues until all radicals react to diamagnetic products (not shown in Figure 2). According to spin-sorting process described above, the time evolution of CIDNP has the shape depicted in Figure 3a. After a fast rise of the geminate stage, a slow decay of equal amplitude during escape reactions leads to compensation of CIDNP (black line). During the radical lifetime, nuclear spin lattice relaxation under influence of the unpaired electron (paramagnetic nuclear relaxation) is operative reducing the polarization in the radicals. Electron spin relaxation times are of the order of 10^{-6} s, while nuclear spin relaxation in

Figure 3 Kinetics of CIDNP, taking into account second-order radical recombination with the parameter $(R_0 \times k_t)^{-1} = 10 \mu s$ (black line), plus nuclear relaxation in radicals with $T_1 = 50 \mu s$ (red line), plus polarization generation in F-pairs with $\gamma = 3$ (blue line). All kinetics start with fast formation of the geminate polarization (a). Kinetics of CIDNP calculated at different values of T_1 (b), $R_0 \times k_t$ (c), and γ (d).

free radicals takes approximately 10^{-4} s. In contrast, the polarization in the diamagnetic reaction product relaxes at a much slower pace (diamagnetic relaxation). The paramagnetic relaxation leads to non-compensated polarization of the products at the end of the radical reaction (red line). Radicals form RPs in the bulk (so-called F-pairs) either in singlet or triplet state. For F-pairs in triplet T_0 state, the same rules of spin sorting as for the geminate RP are valid. Thus, F-pair polarization adds an increasing contribution into CIDNP (blue line).

In the case of cyclic reactions, the procedure of evaluating the CIDNP kinetics is described in Refs 22, 23. It is based on the set of differential equations suggested by Fischer.^{24,25} The polarization of one of the products in cyclic reaction (Figure 2) after the geminate stage is given by the following set of equations:

$$R(t) = \frac{R_0}{1 + k_t R_0 t} \quad (4)$$

$$\frac{dP(R)}{dt} = -k_t P(R)R - k_t \beta R^2 - \frac{P(R)}{T_1} \quad (5)$$

$$\frac{dP(\text{Pr})}{dt} = k_t P(R)R + k_t \beta R^2 \quad (6)$$

The formation of geminate RPs via triplet quenching is assumed to be instantaneous. Here, R_0 is the initial RP concentration, $R(t)$ the concentration of radicals (of the dye D or quencher Q) in the cyclic reaction, $P(R)$ the polarization of the radicals, $P(\text{Pr})$ the polarization of the diamagnetic products (which coincide with the initial species), k_t the rate constant of radical termination, and T_1 the paramagnetic nuclear relaxation time. Parameter β denotes the polarization per RP created in the so-called F-pairs. It is related to the geminate polarization P^G via the quantity γ , which denotes the ratio of polarization created in F-pairs with respect to the geminate polarization: $\beta = \gamma P^G / R_0$.²⁵ For a triplet precursor and a purely random statistics, $\gamma = 3$ is expected. In accordance with literature,^{24,25} $\gamma = 2.8$ was generally used.

In Figure 3, plots b, c, and d show how different parameters determine CIDNP kinetics. With the set of equations (4–6), CIDNP kinetics were calculated at different values of paramagnetic relaxation time T_1 (Figure 3b), of second-order termination reaction parameter $R_0 \times k_t$ (Figure 3c), and of different γ

values (Figure 3d); the CIDNP amplitudes formed after geminate stage of the reaction are set to unity. Thus, the shape of the kinetics is determined by three parameters: T_1 , $R_0 \times k_t$, and γ . The value of stationary CIDNP relative to the geminate polarization depends on the ratio of paramagnetic relaxation time and the radical lifetime. Relaxation destroys “escape” nuclear polarization during the radical lifetime. The more efficiently this CIDNP is destroyed, the higher is the stationary value of polarization (Figure 2).

The above considerations are valid for the case of triplet precursor. If the RP is born in singlet state, $\gamma = -1$. In this case, stationary CIDNP is much lower than the geminate one; its value and sign depend on nuclear paramagnetic relaxation time and radical lifetime. An example of such kinetics is shown in Figure 3d. However, CIDNP resulting from singlet precursor is very low, and there are no relevant examples in the literature. That is why CIDNP from singlet SCRPs is not described in details.

In noncyclic reactions, the equations become more complex and must be derived according to the reaction scheme.^{24,26,27} Below, CIDNP kinetics for cyclic and noncyclic reactions are presented using photoreactions of guanosine-52-monophosphate as an example. Before that, let us describe TR-CIDNP experimental setup.

2.4.2 The Time-Resolved CIDNP Experiment

In Figure 4, the typical TR-CIDNP setup is shown. It consists of FT-NMR spectrometer and pulsed laser. A probe head contains light guide for light irradiation of the sample from the side. The light of the laser is focused on the end of a light guide inserted in the probe head by an optical system, for example, by a quartz lens and a prism. The light guide is a cylindrical quartz rod with the upper end cut under 45° . This surface acts as a mirror to deflect the light by 90° , as it is done in the prism. The convex surface of the quartz rod acts as a cylindrical lens. After reflection on upper surface, the light beam is concentrated to achieve the optimal irradiation conditions of the sample. Another possibility of irradiation with a system of mirrors or prisms to route light to the NMR sample from above²⁸ is applicable for shared NMR

Figure 4 Scheme of the time-resolved CIDNP setup with side irradiation.

spectrometers equipped with multiuser multinuclear probes that could not be modified to permit sample irradiation.²⁹

The time sequence of the measurements is shown in Figure 5. The sample in the NMR spectrometer is irradiated by the laser. Before applying the laser pulse, it is advantageous³⁰ to remove any equilibrium polarization or residual CIDNP from the preceding sequence by a train

of homonuclear saturation pulses provided by the instrument's decoupler. This presaturation takes a few seconds and has the advantage that only pure CIDNP signals appear in the final spectrum. Shortly after the laser pulse is fired to initiate the RP reaction, and during an appropriate and variable delay, τ , the light-induced reactions evolve. Then a radiofrequency (RF)-pulse is applied to measure the magnetization of

Figure 5 Pulse diagram of the TR-CIDNP experiment. The time axis has a nonlinear scale.

the diamagnetic polarized products formed during τ . For increasing the time resolution, although usually the duration of the pulse is much smaller than the duration of a $\pi/2$ flip angle, signal intensity is sacrificed. The free induction decay (FID) is acquired in the normal way and the experiment is repeated to obtain the desired signal-to-noise ratio. A kinetic profile of the appearance of the polarized products is obtained by varying τ .

This experiment monitors only the rates of formation of the final diamagnetic products. The paramagnetic intermediates cannot be seen as their spectral lines are much wider and shifted out of the excitation range. A “snapshot” picture of the reaction is taken at the time τ , representing the polarization of the products at that particular time. Any products formed after the RF-pulse are not seen because their magnetization remains parallel to the main applied field B_z and does not induce any voltage in the probe coil. The nuclei in the free radicals are not excited by the RF-pulse because their resonance frequencies are shifted by the HFI as compared to diamagnetic molecules.

The time resolution of the experiment depends on both the excitation and probing pulse widths. Here, the laser pulse is short (~ 10 ns) and the limit is determined by the length of the RF-pulse. In the examples given below, an RF-pulse of $1\ \mu\text{s}$ was used. The timing usually refers to the center of the RF-pulse, that is, $0.5\ \mu\text{s}$ for $\tau = 0$, and so on on all CIDNP plots below.

2.4.3 Proportionality Relation Between Geminate CIDNP and Hyperfine Coupling Constant (HFCC)

Since ISC in RPs (which is the cause of CIDNP effects) is conditioned by HFIs in the RPs, CIDNP of the diamagnetic products of radical reactions is exploited for the purpose of determination of the HFCCs of the radical intermediates. Thus, CIDNP gives an NMR method to determine the EPR parameters of elusive radical species. Individual nuclei in the radicals are polarized according to their HFI with the unpaired electron and, thus, to the spin density distribution. Together with high-resolution NMR detection, it allows atomic resolution and permits elucidation of the reaction mechanisms and a straightforward assignment of

HFCCs to the structure of reactive intermediates. If the nuclear spins in the reaction product are weakly coupled, the NMR lines belonging to different nuclei do not overlap and net CIDNP of each nucleus is exactly given by integration over all lines of the corresponding spin multiplet. A simple proportionality relation between net geminate CIDNP of a nucleus and its HFCC at the radical stage was established theoretically for short-lived RPs in low-viscosity solution.³¹ The applicability range of this relation was determined: the relation is fulfilled in the case of large difference in g -factor between the radicals involved and for the situation where the number of magnetic nuclei in the system is sufficiently large. The validity of the relation was confirmed by TR-CIDNP experiments on RPs with precisely known HFCCs.³¹ An important extension of the method is a way to determine not only the relative HFCCs but also the absolute ones by analysis of the geminate CIDNP. This becomes possible if one of the partner radicals has precisely known HFCCs and therefore can be used for calibrating the CIDNP dependence. As an example, Figure 6a shows ^1H CIDNP spectrum taken with zero delay after laser pulse in the photoreaction of 3,3',4,4'-tetracarboxybenzophenone (TCBP) and L-methionine–L-glycine (Met–Gly). Polarization of methionine is detected for protons in α , γ , and δ positions of methionine residue, but not in β position, which is characteristic pattern for cyclic transient radical.³² Since integrated over individual signals, net CIDNP formed in a pair of anionic radical of TCBP and cyclic radical of amino acid shows perfect linear dependence on HFCCs of the former (Figure 6b) that are known very precisely from time-resolved EPR; this dependence allows one to determine HFCCs with the protons on the counterpart cyclic transient radicals of methionine moiety using their CIDNP signals. The determined HFCCs are 0.87, 0.78, and 0.72 mT for α , δ , and γ protons, respectively.

The proportionality relation described here is applicable only to analysis of geminate spectra and if the nuclear spins in the reaction product are weakly coupled. In this case, the NMR lines belonging to different nuclei do not overlap and net CIDNP of each nucleus is exactly given by integration over all lines of the corresponding spin multiplet. For strongly coupled nuclei, their CIDNP pattern strongly depends on flip angle of magnetization vector, and information about the

Figure 6 (a) Geminate CIDNP spectrum obtained in electron-transfer reaction between triplet TCBP and Met-Gly; the compliance between NMR signals of diamagnetic products and the protons in intermediate radicals is shown by arrows. (b) Linear dependence HFCCs of TCBP anion radical on CIDNP intensity that allows determination of HFCC with protons in cyclic radical of the methionine moiety in peptide.

sum of HFCCs of the coupled nuclei only can be extracted without analysis of the flip angle dependence used for FT-NMR detection.^{6,7,33}

2.4.4 Kinetic Considerations—Cyclic Reactions

As an example, let us consider the hydrogen atom transfer from guanosine-5'-monophosphate (GMP) to triplet excited 2,2'-bipyridyl (DP) where, at pH 7.5, the neutral radical of guanosine G(−H)• is formed³⁴:

No transformation of this radical occurs at neutral pH, and it is converted back to diamagnetic molecule in the reaction with DP radical. In this case, CIDNP kinetics of GMP could be described by (4–6).

The structures of the initial compounds and of the guanosyl radicals at different pH are shown in Figure 7a. The only nonexchangeable proton of guanyl is H8. CIDNP spectrum obtained immediately after the laser pulse in photoreaction of GMP and DP is shown in Figure 7b. Emission is

observed for H8 of GMP while enhanced absorption is observed for H3, H4, and H5 of DP. The signs of CIDNP are in accordance with Kaptein's rules. CIDNP kinetics shown in Figure 7c (black circles) was simulated using (4–6). The following parameters resulted in best fit (black line): $T_1 = 20 \mu\text{s}$, $(R_0 \times k_t)^{-1} = 45 \mu\text{s}$. The parameter $\gamma = 2.8$ was used.

2.4.5 Cyclic Reaction with Degenerate Electron Exchange

The reaction of degenerate electron exchange (DEE) is operative under the conditions when the radical and its parent molecule represent a system where one of the particles is an electron deficient analog of the other. Matching these conditions requires that the radical is created by electron transfer in the primary photochemical step, and that it is neither protonated nor deprotonated. Another possibility is the radical formation via hydrogen atom transfer and subsequent protonation or deprotonation. Here, to illustrate the influence of the DEE reaction on CIDNP kinetics photoreaction of DP with GMP at pH 1.3 is chosen. At this pH, positively charged GMP (GH^+) quenches positively charged triplet

Figure 7 (a) The structures of 2,2'-bipyridyl and guanosine-5'-monophosphate, and the radicals of guanosine-5'-monophosphate at different pHs. (b) 200 MHz ¹H CIDNP spectrum, obtained in the photoreaction of 2,2'-bipyridyl and guanosine-5'-monophosphate at pH 7.5 with a detecting RF-pulse of 1 μs immediately after the laser pulse. (c) ¹H CIDNP kinetics of H8 of guanosine-5'-monophosphate, obtained during the photoreaction of 2,2'-bipyridyl and guanosine-5'-monophosphate at the concentration of 20 mM at pH 7.5 (black circles), 6 mM at pH 5.0 (red circles), 3 mM at pH 1.3 (blue open circles), and 6 mM at pH 1.3 (blue solid circles). Solid lines—model simulations (see text for details).

excited DP via electron transfer. Guanosine dication radical is formed³⁴:

In the reaction of DEE, no net chemical transformation occurs. However, in this reaction nuclear polarization (denoted by asterisk below) is transferred from the radical to a diamagnetic molecule.

This polarization, which is opposite in sign to the geminate one, superimposes the latter, leading to efficient CIDNP cancellation. For the description of CIDNP kinetics in the presence of DEE, an additional term should be incorporated into equations for nuclear polarization in the radical and in the product. Since the concentration of radicals is usually much smaller than that of

parent molecules, DEE is treated as irreversible pseudo-first-order reaction with the rate proportional to the concentration of molecules (*C*) involved in the exchange reaction with second-order rate constant *k_{ex}*:

$$\frac{dP(R)}{dt} = -k_t P(R)R - k_t \beta R^2 - \frac{P(R)}{T_1} - k_{\text{ex}} CP(R) \quad (7)$$

$$\frac{dP(\text{Pr})}{dt} = k_t P(R)R + k_t \beta R^2 + k_{\text{ex}} CP(R) \quad (8)$$

CIDNP kinetics obtained at different concentrations of GMP are shown in Figure 7c by blue symbols. The typical decay is seen, with the decay rate and stationary CIDNP value proportional to the concentration of the starting compound. CIDNP kinetics was simulated with the following parameters: *T₁* = 20 μs, (*R*₀ × *k_t*)^{−1} = 40 μs, *k_{ex}* = 1.3 × 10⁸ M^{−1} s^{−1}.³⁴

2.4.6 Cyclic Reaction with Degenerate Electron Exchange and Deprotonation

When the radical formed in the primary photochemical reaction step and involved in DEE is not an equilibrium particle, equilibration reaction (protonation of deprotonation) locks DEE. The ratio of equilibration time and the characteristic times of the bulk reactions determines CIDNP kinetics. Below, two cases are considered.

“Slow” Deprotonation

At pH 5, triplet excited DP is quenched by GMP via electron transfer. Cation radical of guanosine G^{+} is formed, which is involved into DEE with the parent molecule G. The rate constant of DEE is $k_{\text{ex}} = 1.3 \cdot 10^8 \text{ M}^{-1} \text{ s}^{-1}$. The radical cation G^{+} has $pK_a = 3.9$, and at pH 5 deprotonates to form neutral radical $G(-H)^{\bullet}$:

Neglecting the difference in recombination rate constants in two pairs of radicals, the concentrations of the dye R_D , cation radical of GMP R_1 , and neutral radical R_2 are as follows:

$$R_D(t) = \frac{R_0}{1 + k_t R_0 t} \quad (9)$$

$$R_1(t) = \frac{R_0 e^{-k_d t}}{1 + k_t R_0 t} \quad (10)$$

$$R_2(t) = \frac{R_0(1 - e^{-k_d t})}{1 + k_t R_0 t} \quad (11)$$

Here, k_d is the rate constant of deprotonation reaction.

The following equations describe polarization in two types of quencher radicals and in corresponding products:

$$\begin{aligned} \frac{dP(R_1)}{dt} &= -k_t P(R_1) R_D - k_t \beta_1 R_1 R_D \\ &\quad - \frac{P(R_1)}{T_1} - k_{\text{ex}} CP(R_1) \end{aligned} \quad (12)$$

$$\frac{dP(\text{Pr}_1)}{dt} = k_t P(R_1) R_D + k_t \beta_1 R_1 R_D + k_{\text{ex}} CP(R_1) \quad (13)$$

$$\frac{dP(R_2)}{dt} = -k_t P(R_2) R_D - k_t \beta_2 R_2 R_D - \frac{P(R_2)}{T_1} \quad (14)$$

$$\frac{dP(\text{Pr}_2)}{dt} = k_t P(R_2) R_D + k_t \beta_2 R_2 R_D \quad (15)$$

In the CIDNP experiment, the sum $P(\text{Pr}_1) + P(\text{Pr}_2)$ is detected. Since CIDNP enhancement coefficients formed in the two types of RPs may differ, two parameters R_1 and R_2 were used. No difference in nuclear paramagnetic relaxation times for different guanosine radicals was found, so only one value of T_1 is taken into account.

CIDNP kinetics obtained in photoreaction of GMP and DP at pH5 is shown in Figure 7c (red symbols). It is seen that initial decay is changed to a growth, indicating DEE termination upon deprotonation. The parameters of simulation are as follows: $T_1 = 20 \mu\text{s}$, $(R_0 \times k_t)^{-1} = 114 \mu\text{s}$, $k_{\text{ex}} = 3 \times 10^8 \text{ M}^{-1} \text{ s}^{-1}$, $\gamma_1 = 2.8$, $\gamma_2 = 2.2$, $k_d = 1.6 \times 10^6 \text{ s}^{-1}$.

“Fast” Deprotonation

The example of CIDNP kinetics detected in case of fast deprotonation of the radical is given in the section “Applications of CIDNP,” where photoinduced reaction between triplet excited 4-carboxybenzophenone and glycylglycine dipeptide is described.

3 CIDNP—EXAMPLES

3.1 Steady-State CIDNP of Organic Radicals and Radical Ions

Photo-triggered reactions have been utilized for the generation of short-lived species in a variety of fields. A frequently followed procedure to attain reactive organic radical cations is light excitation of mixtures of efficient electron acceptors, for example, benzoquinone, its derivative chloranil (2,3,5,6-chloro-1,4-benzoquinone) or DDQ (2,3-dichloro-5,6-dicyanobenzo-1,4-quinone) together with the oxidizable substrate. Such reaction mixtures result in the formation of radical (ion)

Scheme 3 Formation of radical-ion pairs.

pairs. Obviously, electron-transfer procedures also can lead to neutral, or differently charged radicals, depending on the character of the parent reactants (Scheme 3).

In most cases, electron transfer proceeds after ISC from an excited singlet to the triplet state. In terms of organic radical cations, pioneering work was contributed by H. D. Roth.^{35–37} Out of many radical cations investigated by Roth and coworkers, a few representative examples are introduced here, to show the scope of this method. One such example is the question of whether homoaromaticity exists; that is, can non-directly bonded molecular moieties carrying a double bond interact “through space”? One of the classical examples in this respect is norbornadiene (ND). A ¹H-CIDNP experiment performed with chloranil or 1-cyanonaphthalene yields a polarization pattern indicating that the radical cation ND^{•+} possesses two indistinguishable ethene moieties, thus indicating a homo-delocalized π system. It is even more remarkable that photolysis of the ND isomer quadricyclane QC leads to ND; however, the intermediate radical cation QC^{•+} reveals a different electronic structure than ND^{•+} (Figure 8; one could also call them homo σ - and homo π -aromatic, respectively).

A wide variety of functional molecules like drugs or antioxidants contain amino groups. Since, the primary reaction of the amino moiety generally is electron transfer leading to the formation of

Figure 8 Different structures of the radical cations generated from norbornadiene and quadricyclane.

a (predominately) nitrogen-centered radical cation, CIDNP is a very well-suited method for the investigation of the follow-up reactivity of the short-lived amino radical cations. Already in the early years of CIDNP, the reactions between (tertiary) amines and electron acceptors were investigated.^{38,39} Generally, an initial amine radical cation deprotonates forming an α amino carbon-centered radical, which further leads to the parent amine and an alkene via well-established radical disproportionation as well as recombination products (depending on the steric situation) as shown in Scheme 4.

Several research groups have investigated the reactivity of amines with a variety of electron-transfer agents. Besides electron transfer, also hydrogen abstraction can occur. The nature of the solvent and the acceptor A (e.g., 9,10-anthraquinone or benzophenone derivatives) play a decisive role for the lifetime of the initially formed radical-ion pair (Scheme 4) and its follow-up reactivity. A more detailed account on these reaction patterns was elaborated by Roth.⁴⁰

Scheme 4 Simplified reaction sequence for the electron-transfer reaction between an amine and an electron acceptor (A). The reactions at the triplet and singlet domain are omitted; see text.

3.2 Photoinitiators and Radical Polymerization

It is obvious that the CIDNP technique is also rather helpful for the investigation of systems, which show α -cleavage (or a Norrish type I reaction). In the predominant number of cases, such molecules consist of a (substituted) benzoyl moiety attached to a molecular entity, which is able to form short-lived reactive radicals. If such a compound is irradiated at a wavelength where $n - \pi^*$ transitions are excited, homolytic bond cleavage occurs after ISC. The subsequently formed RP is able to initiate follow-up radical reactions (Scheme 5). Accordingly, such photo-triggered reactions can be utilized as photoinitiating systems for polymerizations.

In the early days of CIDNP, it was shown that photolysis of benzyl derivatives leads to well-distinguishable CIDNP patterns.⁴¹ Subsequently, many industrially applied photoinitiators also were investigated.^{42,43} Here, we present an example based on rather efficient photoinitiators consisting of a benzoyl and a phosphinoyl moiety (Scheme 5). On photolysis and ISC, initiator **I** undergoes α -cleavage and the carbon-centered benzoyl radical **B** and phosphorus-centered radical **P** are created. Both radicals are able to act as starters for radical polymerization if an appropriate quencher (e.g., an acrylate) is present.⁴⁴

The reaction sequence displayed in Scheme 5 holds for a variety of initiators.⁴⁵

In the presence of polymerizable molecules, the escape products (Scheme 5) are no more detected. Apart from the CIDNP resonances of “cage” recombinations, polarized signals stemming from products formed during the growth of the polymer chain become visible.⁴² Two predominate features are detected, when benzoyl-based initiators are utilized in the presence of monomers. This is shown in Figure 9.

The first feature, which becomes visible is a well-pronounced polarization of the acrylate and can be rationalized by a reversible addition–elimination of the monomer, a feature observable with a variety of substrates.^{46,47} The second feature is the occurrence of the absorptive resonance at circa 10.5 ppm, indicative of the formation of an (aromatic) aldehyde. Since the aldehyde is formed as an escape product, the initially formed benzoyl radical has to obtain the hydrogen atom from a species that stems from an “escaped” radical. The CIDNP spectra are in line with the assumption that the H atom stems from a growing-chain radical as shown in Scheme 6.

Accordingly, the formation of aldehydes from benzoyl radicals can not be omitted since the bond dissociation energies of the transferable β -protons in PM $\cdot$ and BM $\cdot$ are low.⁴⁶ The reversibility of the initial addition of monomers to initiator radicals can give insights into the molecular basis of depolymerization procedures, which is macroscopically characterized by the ceiling temperature. Moreover, the inclusion of the polymerizable products PM

Scheme 5 α -Cleavage of a phosphine oxide-based photoinitiator and follow-up products (in the absence of a quencher).

Figure 9 ^1H NMR and ^1H CIDNP spectrum obtained after photolysis of bisacylphosphin oxide (BAPO) and butyl acrylate.

and BM can lead to additional functionalization of polymers.

CIDNP can also be utilized to investigate stereo-electronic effects on chemical reactivity. Molecules endo-N and exo-N are stereoisomers. While the benzoyl substituent is oriented at an axial position in endo-N, the axial position of this substituent leads to the orientation of the aromatic moiety away from the bicyclic system in exo-N. These different orientations of the photoactive benzoyl moieties cause dramatic reactivity differences between endo-N and exo-N, whereas no CIDNP effects can be established on photolysis of endo-N (the polycyclic skeleton K can be identified by NMR techniques). As illustrated above, the RP, consisting of the 6-hydroxy-bicyclo[2.2.2]oct-2-en-6-yl ($\text{NR}^\bullet$) and the benzoyl radical, leads to cage and escape products. Besides recombination, rearrangement and disproportionation products are observed. Since $\text{NR}^\bullet$ is essentially planar at the radical center, recombination with the benzoyl radical leads not only to the

restitution of the exo-N but also to the endo isomer (Scheme 7).

3.3 Application of Time-Resolved CIDNP

The examples above demonstrate that CIDNP kinetics is highly sensitive to the rates and mechanisms of radical reactions. Thus, it was successfully used to investigate radical reactions pathways and radical structure. Individual atoms in the radicals are polarized according to spin density distribution that, together with NMR technique of detection allowing atomic resolution, permits elucidation of the reaction mechanisms and the structure of reactive intermediates. The polarization pattern is detected by pulsed NMR method that leads to submicrosecond time resolution. With this time resolution, investigation of such processes as paramagnetic nuclear relaxation for individual nuclei is possible that gives

Scheme 6 Reaction pathway derived from the CIDNP spectra displayed in Figure 8 (for clarity, the addition of further acrylates to $PM\cdot$ and $BM\cdot$ leading to the polymer—still, the dominating reaction—is omitted).

information on intramolecular mobility of polarized parts of the radicals. In addition, CIDNP is one of the few methods that are sensitive to intramolecular electron transfer (IET) and DEE.

3.3.1 Photoreactions of Glycylglycine

Electron transfer from the lone pair on the nitrogen atoms of the peptide backbone to oxidizing agents is recognized as one of the major contributions to protein degradation. The oxidation process primarily leads to formation of aminium radical cations. These are highly reactive and very short-lived intermediates, and as a result they have

eluded electron spin resonance (ESR) detection in numerous studies of aqueous solutions of amino acids at room temperature.^{48–51} Instead, the more stable secondary aminyl radical or α -aminoalkyl radicals and products of their decomposition were detected.^{48–51} The quenching mechanism that is electron transfer from the amino group was found to be responsible for the main channel of the reaction of triplet 4-carboxybenzophenone (CBP) with aliphatic amino acids.⁵¹ Evidence for this came from the emergence of the transient absorption spectra of the carboxybenzophenone radical anion on the nanosecond timescale after photoexcitation, but not of the aminium radical. The lack of a suitable chromophore in the aminium radical precludes its

Scheme 7 Photoreactivity of endo- and exo-N.

detection by transient optical absorption. A source of experimental information on such radicals is TR-CIDNP.⁵²

Since oxidized glycine undergoes fast decarboxylation, glycyglycine (Figure 10a) was the simplest and probably the best model system to study this electron-transfer reaction involving the lone pair on nitrogen and photoinitiation with triplet sensitizer (4-carboxybenzophenone, CBP). In the pH range 6–13, nuclear polarization of the dipeptide Gly–Gly was observed only for the α -protons of the glycine residue at the N-terminus (Figure 10b). This observation provides irrefutable evidence that the excited triplet state of 4-carboxybenzophenone reacts with Gly–Gly in aqueous solution via a reductive quenching mechanism from the terminal NH_2 group, and

no quenching reaction takes place from the other residue at the C-terminus. As in the case of glycine, the aminium radical, formed as a result of quenching, undergoes fast deprotonation:

The characteristic deprotonation time τ_d could be estimated using the $\text{p}K_a$ value 2.6 reported for the aminium radical derived from glycine,⁵³ and a typical value of the protonation rate constant

Figure 10 (a) The structure of glycylglycine. (b) 200-MHz ^1H NMR spectrum of glycylglycine and 200-MHz ^1H CIDNP spectrum, obtained in the photoreaction of 4-carboxybenzophenone and glycylglycine at pH 12 with a detecting RF-pulse of 1 μs immediately after the laser pulse. (c) Circles: ^1H CIDNP kinetics of the α -protons at the N-terminus of glycylglycine, obtained during the photoreaction of 4-carboxybenzophenone and glycylglycine at pH. Solid line: model simulation (see text for details).

$k_p = 10^{10} \text{ M}^{-1} \text{ s}^{-1}$; $\tau_d = K_a^{-1} k_p^{-1} \approx 40 \text{ ns}$. Thus, the characteristic time of deprotonation falls in between the characteristic times of geminate reactions and bulk reactions. The kinetic data obtained are in agreement with a fast deprotonation to the aminyl radical; otherwise, a fast decay of the CIDNP kinetics would be expected which is determined by DEE.^{23,54} In the present case, the geminate RP and RPs in the bulk are different due to deprotonation of the aminium radical. In order to take this into account in the kinetic simulations, the intensities of polarization of α -protons at the N-terminus were calculated using the Adrian model⁵ for the two types of RPs with triplet precursor. Both pairs contain the anion radical of carboxybenzophenone, and aminium radical or amino radical as a partner. The CIDNP intensity for the α -protons in the pair with an aminyl radical was found to be 3.4 times higher than that with the aminium one; therefore, $\gamma = 3.4 \times 2.8 = 9.6$ was used. Such a high value provides more than fourfold CIDNP growth. Variation of T_1 in the range 20–40 μs resulted in good coincidence between experiment

and simulation. Other parameters of simulation are $T_1 = 25 \mu\text{s}$, $(R_0 \times k_t)^{-1} = 63 \mu\text{s}$ (Figure 10c).

3.3.2 Photoreactions of Sulfur-Containing Biologically Important Molecules

TR-CIDNP was successfully applied to study of the reactions of radical intermediates of methionine,⁵⁴ 3-(methyl)thiopropylamine,⁵⁴ Met–Gly,³² and Gly–Met³² with 4-carboxybenzophenone, 3-carboxybenzophenone, 3,3',4,4'-benzophenone-tetracarboxylic acid, and 9,10-anthraquinone-2-sulfonate in aqueous solution at different pHs (6.7–13.3). The obtained results give clear evidence that two oxidative quenching mechanisms formally attributed to electron abstraction from sulfur and nitrogen atoms are operative in reactions with excited triplet states of suitable acceptor molecules. Thus, the structure of the methionine radical cations derived from the free amino acid or the dipeptides depends on the pH. After electron transfer from the sulfur atom to the triplet excited dye molecule, two structures of the radical cation having different

distributions of spin density are formed. At pH values above the pK_a of the amino group, the Met radical cation exists in a cyclic form with a two-center, three-electron bond between the nitrogen and sulfur atoms, while in solutions below pK_a the Met radical cation has an “open form” structure. The same behavior is observed for 3-(methylthio)propylamine. The comparison of the TR-CIDNP results with literature data obtained by steady-state CIDNP measurements⁵⁵ casts doubt on the hypothesis that interconversion between three types of methionine cation radicals occurs. Instead, a competitive channel for oxidative quenching of the triplet sensitizer by direct electron transfer from the nitrogen atom leading to formation of the aminium radical cation was revealed that is operative in strongly basic solution. The study of the CIDNP kinetics formed in the photoreaction of 3-(methylthio)propylamine and methionine at strongly basic condition shows a much higher efficiency of polarization in the aminyl radical than in the two other species, the aminium and cyclic radicals.⁵⁴

In the case of the dipeptides, the reactions are more complex.³² Gly–Met form S-centered radicals at all pHs, whereas the Met–Gly only at a pH below 4.5. At a pH above 4.7, a cyclic radical with a two-center, three-electron bond between the N and S atoms is formed for the case of Met–Gly, but not for Gly–Met. In neutral solution, at a pH above 4.5 but below the pK_a of the amino group Met–Gly forms first S-centered radicals, which undergo deprotonation on the microsecond scale with formation of the cyclic radical. In basic solution (pH > 11), the existence of a channel of oxidative quenching via electron transfer from the lone electron pair of nitrogen of the amino group was revealed for both Met and Gly allowing to suggest that it is a common feature of all amino acids and proteins. The CIDNP kinetics of Met–Gly and Gly–Met showed that in basic solution the aminium radical deprotonates on the submicrosecond timescale forming the aminyl radical.³²

The TR-CIDNP measurements also allow demonstrating the crucial influence of the DEE between cationic radicals (or dimers) and diamagnetic molecules on the intensity of the CIDNP signals in the pH range below the pK_a of the amino group of methionine.⁵⁴ The rate constant for the electron exchange was obtained. The kinetics of the polarization in the 3-(methylthio)propylamine chosen as a

model compound to study magnetic resonance properties in cyclic five-membered ring radicals allows to determine the paramagnetic nuclear relaxation time T_1 for α and γ protons and to show that protons in the vicinity of the nitrogen have a much faster relaxation than the other protons. Kinetic parameters were also obtained for both dipeptides in neutral and basic solutions.³²

The polarization of the Gly residue occurs only when it is located at the N-terminus of the protein. The position of the Met residue, whether it at the N-terminus, the C-terminus or in the middle of the protein, can be derived from the polarization pattern: the α proton is polarized only at the N-terminus and not polarized in the other cases.

3.3.3 Time-Resolved CIDNP as a Tool to Study Inter- and Intramolecular Electron-Transfer Reactions

Among processes that are important in biological systems is charge migration in the oxidized species. To understand the factors that govern such processes, monitoring the radicals during their lifetime is necessary. Transient optical spectroscopy is not always applicable for that since not all the radicals are good chromophores. CIDNP offers a good alternative: enhancements are observed for NMR signals of nuclei that have nonzero HFI constants in transient radicals. The essence of TR-CIDNP method in investigation of the reductive electron-transfer reactions is in spin-sorting nature of $S-T_0$ mechanism of CIDNP formation. As described in detail above, the geminate stage of the reaction, nuclear-spin-dependent ISC, and spin-selective recombination give rise to the geminate CIDNP. Radicals that escape geminate termination are “marked” by nuclear polarization that is opposite in sign to the geminate one. When the reductive electron transfer takes place, this CIDNP superimposes the geminate polarization leading to CIDNP decay. This CIDNP cancellation effect is very similar to that observed in the CIDNP kinetics when DEE is operative. The difference from DEE is that in the type of the reaction considered not only the polarization is transferred from the radical to a diamagnetic molecule, but the radical itself decays that closes the possibility for the formation of additional CIDNP in the F-pairs. This is taken into

account in the equations describing CIDNP kinetics. As shown below, CIDNP kinetics is highly sensitive to the rate of the reductive electron transfer so that it is possible to study this reaction quantitatively by analyzing CIDNP kinetics.

3.3.4 Intramolecular Electron Transfer in Dipeptides His-Tyr and Tyr-His

Indirect evidence for the proton coupled electron transfer from tyrosine to the histidyl radical was drawn only from optical detection of tyrosyl radicals. The CIDNP technique allows one to follow the reactions of transient histidyl radical using NMR detection of histidine signal.^{22,56} The CIDNP-detected kinetics of H2 of His residue is shown in Figure 11a. The polarization decay is typical of reductive electron transfer to the radical the product of which is observed.^{23,57–60} For comparison, the kinetics of the photoreaction between DP and the peptide histidine-phenylalanine (His-Phe) is shown. The CIDNP of H2 of the histidine residue in His-Phe is observed to increase in time (black circles in Figure 11a). Therefore, the CIDNP

decay observed for H2 proton of His residue in the photoreactions of the peptides His-Tyr and Tyr-His can be attributed to the reaction of IET from the tyrosine residue to the histidyl radical. The rate constant of IET from tyrosine residue to histidine radical is denoted as k_e . The general reaction is

The equations describing the observed CIDNP kinetics are the following:

$$R_D(t) = \frac{R_0}{1 + k_t R_0 t} \quad (18)$$

$$R_1(t) = \frac{\alpha R_0 e^{-k_e t}}{1 + k_t R_0 t} \quad (19)$$

$$\begin{aligned} \frac{dP(R_1)}{dt} = & -k_t P(R_1) R_D - k_t \beta R_1 R_D \\ & - \frac{P(R_1)}{T_1} - k_e P(R_1) \end{aligned} \quad (20)$$

Figure 11 (a) ^1H CIDNP kinetics for the H2 proton of histidine residue in His-Phe (black circles), Tyr-His (red circles), and His-Tyr (blue circles), obtained during the photoreaction between 2,2'-bipyridyl and the corresponding dipeptide at pH 7.3. (b) ^1H CIDNP kinetics for the proton H8 of GMP obtained at pH 7.5 in the photoreactions of 2,2'-bipyridyl with GMP (black circles), with GMP in the presence of 2.5 mM of *N*-acetyl tyrosine (red circles), and with GMP in the presence of 2.5 mM of *N*-acetyl tryptophan (blue circles). Solid lines—model simulations (see text for details).

$$\frac{dP(\text{Pr}_1)}{dt} = k_i P(\text{R}_1) R_D + k_i \beta R_1 R_D + k_e P(\text{R}_1) \quad (21)$$

Since both residues, His and Tyr, participate in the quenching reaction with the formation of corresponding radicals, the parameter α is used, which is the share of histidyl radicals.

The best-fit simulations are shown in Figure 11a by solid lines. The best-fit values of $(R_0 k_i)^{-1}$ are 23 μs for Tyr–His and 34 μs for His–Tyr. The rate constants of IET are $(7.5 \pm 1.5) \times 10^4 \text{ s}^{-1}$ and $(3.8 \pm 0.8) \times 10^5 \text{ s}^{-1}$ for the oxidized Tyr–His and His–Tyr, respectively.⁶¹

3.3.5 Modeling of Non-Enzymatic DNA Repair by Electron Transfer from Amino Acids to Guanosyl Radicals

Electronic vacancies on the guanyl base in DNA produced by oxidizing agents or by ionizing radiation may be refilled rather fast via electron transfer from the surrounding protein pool, thus preventing the radical chemistry to evolve into pathological DNA damage. As a model of chemical DNA repair, the reductive electron transfer to the free radical of the GMP from *N*-acetyl derivatives of amino acids tyrosine and tryptophan was studied.^{23,60} The guanosyl radicals were photochemically generated in the quenching reaction of the triplet excited dye 2,2'-bipyridyl.

The kinetic data for the reductive electron transfer between photochemically generated GMP radicals and *N*-acetyl tryptophan or tyrosine demonstrate that for both amino acids the reaction rate constants are dependent on the protonation state of the reacting species.^{23,60} The example in Figure 11b shows CIDNP kinetics, obtained in photoreaction of GMP in the presence of *N*-acetyl derivatives of tyrosine and tryptophan at pH 7.5. The decay observed in CIDNP kinetics of GMP in the presence of the amino acids compared to CIDNP kinetics of GMP when no amino acid is added unambiguously proves that electron transfer to guanosyl radical takes place. The rate constants of this reaction obtained from the simulation of CIDNP kinetics are $(6.0 \pm 1.0) \times 10^7 \text{ M}^{-1} \text{ s}^{-1}$ (*N*-acetyl tyrosine)²³ and $(2.6 \pm 0.4) \times 10^8 \text{ M}^{-1} \text{ s}^{-1}$ (*N*-acetyl tryptophan).⁵²

The detailed kinetic investigation of four forms of elusive radical intermediates of GMP subject to the reductive electron transfer from the amino acids in aqueous solution at ambient temperature was possible because of the very strong enhancement of NMR signals by chemically induced dynamic nuclear polarization in the reaction of the triplet dye DP with both GMP and each of the two amino acids. For both amino acids, our data show that the different forms of GMP radicals, namely, $\text{GH}^{++\cdot}$ (pH 1.3), $\text{G}^{+\cdot}$ (pH 2.9), $\text{G}(-\text{H})^{\cdot}$ (pH 7.5, 11.0, 11.3), and $\text{G}(-2\text{H})^{-\cdot}$ (pH 13.3), are characterized by a different oxidative property with rate constants changing from $(1.0 \pm 0.3) \cdot 10^9 \text{ M}^{-1} \text{ s}^{-1}$ as obtained for $\text{G}^{+\cdot}$ and $\text{GH}^{++\cdot}$ with *N*-acetyl tryptophan⁶⁰ to a value of less than $6.0 \times 10^6 \text{ M}^{-1} \text{ s}^{-1}$ for the reduction of $\text{G}(-2\text{H})^{-\cdot}$ by *N*-acetyl tyrosine.²³ The common feature for reductive electron transfer is that the reaction proceeds with much higher efficiency in acidic conditions. For tryptophan, the reaction proceeds with a higher efficiency than that for tyrosine, and is of much higher efficiency at neutral and basic conditions.

A quantitative analysis of photoinduced bidirectional IET between tryptophan and tyrosine moieties at strongly acidic conditions using the high potential of TR-CIDNP is used in determination of radical reaction mechanisms and absolute rate constants. The CIDNP kinetics obtained in photoreactions of 2,2'-bipyridyl with the tryptophan–tyrosine peptide proved to be very sensitive to the IET in the peptide.⁶²

In reactions with the two residues, the sign of the dye polarization (emissive in the pair with tryptophanyl and absorptive in pair with tyrosyl) is a characteristic and sensitive indicator that allows one to elicit the direction and efficiency of IET. It was possible to extract the rate constants of IET in both directions, k_f and k_r , from the tyrosine to the tryptophan radical moiety, and from the tryptophan to the tyrosine radical moiety, respectively. In acidic solutions with pH varying from 1.6 to 2.4, k_f remains constant, while k_r changes. The differences between the one-electron reduction potentials of the tryptophanyl and tyrosyl radicals in the peptide were obtained from the value of the equilibrium

constant $K = k_f/k_r$, which showed a good linear dependence on pH with a slope equal to unity.⁵⁴ Application of TR-CIDNP to photoreactions of protein, hen egg white lysozyme, allowed to reveal that intramolecular electron transfer between tyrosine residues and tryptophan radicals in denatured lysozyme is highly efficient and partially reversible; also, there is a reaction of electron transfer from tryptophan residues to tryptophan radicals (this electron exchange is not fully degenerate).⁶³ These reactions affect the CIDNP kinetics so that tyrosine signals increase in time, and tryptophan signals decay rapidly.⁵⁹ Thus, geminate CIDNP spectra differ substantially from stationary spectra. It therefore appears that it is IET that leads to the observation of low CIDNP intensity for tryptophan residues relative to tyrosine residues in steady-state spectra rather than hydrophobic clustering as suggested earlier, although observation of IET does not exclude the existence of hydrophobic clustering. CIDNP spectra recorded immediately after a short laser pulse may thus allow a more reliable assessment of the surface accessibility of amino acid residues in proteins.

3.3.6 Interactions in Biomacromolecules

The principles of creating polarized NMR spectra can be advantageously utilized to gain insight into the fluid-state behavior of biomacromolecules. Here, we present illustrative examples from many investigations to indicate the scope of this experimental approach. Generally, proteins contain tyrosine, tryptophan, and histidine residues. Particularly, these amino acids are able to undergo reactions compatible to those shown in the previous chapters. On irradiation in the presence of a suitable dye (flavin derivatives are frequently used here), these amino acids can undergo electron or hydrogen atom transfer reactions, which lead to RPs as intermediates. Importantly, the spin distribution and the electronic structures of the amino acids lead to well-distinguishable polarizations in their NMR spectra. Moreover, specific chemical shifts of, for example, the tyrosine proton resonances help to identify the exact location at which radical formation takes place (particularly, the 3 and 5 positions of tyrosine). Pioneering work for establishing this principle was reported by Kaptein and coworkers.⁶⁴ Accordingly, this procedure has been utilized in many investigations.

Particularly valuable information on the accessibility of specific residues in complex biological structures can be gained by CIDNP since these experiments are performed on fluid samples at ambient conditions. Therefore, the limitations of solid-state-based methods like X-ray structure analysis do not exist and dynamic properties of, for example, proteins can be accessed.^{9,65}

This includes the (surface) accessibility of specific domains,^{66,67} protein structure,^{9,68,69} and folding^{70–74} and, rather recently, it was shown that well-selected Ru(II) complexes can be utilized as sensitizers.⁷⁵

For such protein studies, CIDNP is created by reactions involving reversible electron or hydrogen atom transfer between a photo-excited dye molecule (see above) and CIDNP-active amino acid residues. The polarization of the CIDNP-active residues in the protein depends on their accessibility for the probing dye molecule. The assumption underlying the photo-CIDNP technique is that only residues accessible to the dye molecule acquire substantial polarization. Therefore, one can analyze CIDNP of the protein in order to obtain the accessibilities of residues on the protein surface. However, it should be pointed out that CIDNP in proteins depends not only on the accessibility of the amino acid residues and on the mechanism of photochemical reactions but also on the reactivity of the intermediates and the efficiency of IET.⁵⁷ In the case of real time protein folding detection by CIDNP at the millisecond timescale, the spin polarization does not reflect the folding in a straightforward way since it depends also on the change of the efficiency of IET on the folding and on the dynamics of CIDNP formation on the microsecond timescale. In particular, we want to stress that only geminate, and not stationary, CIDNP should be used to draw conclusions about structural changes in denatured and molten globule states. However, with proper precaution taken, the combination of TR-CIDNP with the initiation of folding in the probe of the NMR spectrometer opens the possibility to follow the protein folding process

by high-resolution NMR selectively enhanced by CIDNP.

4 FIELD DEPENDENCE OF CIDNP

The mixing of the RP state and, hence, the efficiency of the sorting depends on the competition between hyperfine and difference in Zeeman interaction, $|g_1 - g_2|\mu_B B$ (see Figure 1b); thus, the CIDNP effect varies with the external field. In return, this dependence on the magnetic field can be exploited for determining HFI couplings in the radicals as well as differences in their g -factors. Roughly speaking, the maximum NMR enhancement in RP with a single nucleus spin 1/2 is expected when the Zeeman term $|g_1 - g_2|\mu_B B$ is equal to half of the hyperfine coupling, $A/2$. RP can contain many nuclear spins whose hyperfine couplings increase the local magnetic field. Consequently, the position of CIDNP maximum is shifted to higher field and maximum broadening by additional HFCCs.

Field-dependent CIDNP measurements were carried out using a mechanical field cycling setup driven by a computer-controlled step motor device positioning of the whole NMR probe⁷⁶ or irradiation cell combined with injection device within the bore of NMR magnet⁷⁷ that can be utilized for magnetic field from 0.05 to 14 T. Although time resolution is not possible in such experiments and only steady-state polarization is detected, high sensitivity of the CIDNP field dependence with respect to Δg makes the analysis of CIDNP very suitable for characterizing short-lived paramagnetic reaction intermediates. For example, at large g -factors of two methionine radicals, 2.0064 for cyclic radical and 2.0100 for S-centered radical, CIDNP maxima were found at around 2.1 T and 0.7 T, respectively.^{32,78} Examples of radicals of amino acids methionine,⁷⁸ histidine, and⁷⁹ tyrosine,^{18,80,81} and of peptides Met-Gly and Gly-Met³² show that the high field part of CIDNP field dependence when $B \gg A$ is described very well in frame of Adrian model,⁵ allowing to determine Δg value quite precisely.

For RPs with restricted mobility that are being in confined media or connected by chemical bonds forming biradicals, the electronic exchange interaction is important for spin evolution. Field dependence of CIDNP offers the possibility of a direct determination of electronic exchange interaction, J . Depending on the sign of J , the RP singlet level

crosses one of the triplet levels, with T_+ or T_- for positive and negative J , respectively, at magnetic fields $g\mu_B B = 2|J|$ where a resonance-like maximum is formed.^{82–84} Since the total electronic and nuclear spin is conserved in singlet–triplet conversion, the electronic and nuclear spins are flipping together in allowed transitions $S\alpha \rightarrow T_-\beta$ and $S\beta \rightarrow T_+\alpha$. Thus, the sign of nuclear polarization in this case is determined by the multiplicity of precursor μ and by the sign of J , $\Gamma = (\mu)(J)$, and does not depend on the sign of HFCC, in contrast to $S-T_0$ transition at high field for the short-lived RPs. If the multiplicity of the precursor is known from optical data, the sign of J can be determined from the sign of nuclear polarization.⁸³ While position of the maximum can be directly related to the electronic exchange interaction for rigid biradicals, $g\mu_B B = 2|J|$,⁸³ for flexible biradicals that, for instance, are resulting from the photolysis of cyclic aliphatic ketones^{82,85} the situation is much more complex. The spin evolution and molecular dynamics are coupled via modulation of the distance-dependent exchange interaction $J(r)$ by motion of radical centers.^{86,87} As a consequence, the position of CIDNP maximum is dependent on molecular mobility and in gas phase, it is considerably shifted to higher magnetic field.⁸⁴

The theory of RP mechanism of CIDNP predicts that while the high field part of the CIDNP depends on both the difference of g -factors and the HFIs of the radicals, the CIDNP formation in RPs at low field is conditioned solely by the HFI and J . However, quantitative analysis of CIDNP in low field is very complex, because observed polarization depends also on the spin evolution in the diamagnetic molecules, which is a function of the magnetic-field strength. One consequence of this evolution is polarization transfer among nuclei in the molecule,^{88–90} taking place once the nuclei are strongly coupled in the studied magnetic field. (Two spins are considered weakly coupled if the nuclear spin–spin interaction between them is much smaller than the difference in their Zeeman interaction with the external field. In other cases they are considered strongly coupled.) Thus, not the absolute, but only the relative strength of the coupling with respect to difference in Larmor frequency of nuclei is important for fulfilling the strong coupling condition, which therefore depends on the external magnetic field. In addition, nuclear relaxation of scalar coupled of diamagnetic molecules is also field

dependent,^{91,92} even if conditions of fast motion are met. Fast and coherent redistribution of polarization among spins strongly coupled by scalar interactions in diamagnetic products is an inevitable obstacle for low-field CIDNP experiments and plays a negative role since after polarization redistribution unraveling information on reaction pathways and intermediates is obscured and its analysis becomes problematic and ambiguous. Anyway, information about the field dependence of CIDNP is a valuable addition to the data obtainable in the time-resolved mode of CIDNP as considered above. It provides supportive information to interpretation of CIDNP patterns detected in high field.

5 SOLID-STATE CIDNP

In 1994, it was reported, that CIDNP phenomena can be established also in the solid-state magic angle spinning-NMR (MAS-NMR).⁹³ It has been mainly observed in photosynthetic reaction centers (¹³C and ¹⁵N nuclei), which are modified to allow a reversible electron transfer ("cyclic electron transfer").^{94–99} Recently, the MAS CIDNP effect was observed on a blue-light photoreceptor.¹⁰⁰

This technique allows insight into the photochemical background of the reaction in light-harvesting proteins. The theory behind this effect is still under development and relies on different spin-related mechanisms, which exceed the scope of this article^{101–104} and were briefly summarized.¹⁰⁵ Apart from its, yet, limited usability, it will be of interest to follow the development of this method.

6 CIDEP (TIME-RESOLVED EPR)

The phenomenon of CIDEP was reported prior to the discovery of CIDNP.¹⁰⁶ First developed connected to the pulse-radiolytic generation of radicals, it is now predominately used in connection with laser-flash photolysis. Compared with the "usual" continuous wave EPR (cw-EPR), the signals are detected in a nonmodulated manner. In a similar way as described in Section 1.2 of this article, the radicals (RP) are created in a polarized state and, accordingly, non-Boltzmann effects on the applied timescale dominate the signal intensities. Two predominant factors are responsible for the

perturbed intensities, the triplet mechanism (TM) and the RPM. The RPM in CIDEP is analogous to that established in Section 1.2 of this article, but here in contrast to CIDNP, the recombination of the radicals is not required.

The TM is generally detected in systems where radicals are generated by photolysis. After excitation to the excited singlet state, the polarization is built up during ISC to the triplet state. ISC depends on spin–orbit coupling and this interaction is related to the relative orientation of the orbitals involved. On the basis of the nondegeneracy of the triplet components at high magnetic field, each of the three triplet energy levels becomes populated to a different extent (Figure 12); thus, remarkably, the polarization is created even before the radicals are formed.

While the TM leads to identical phases and intensity enhancements of the EPR lines, RPM provides emission *and* absorption contributions. Since both phenomena are time dependent, often different polarization patterns are observed at varying delays of signal acquisition.

The origin of TM and RPM for CIDEP has been developed and reviewed.^{107–112} In the last few decades, additional mechanisms for the creation of polarization have been developed such as the RTPM (radical triplet pair mechanism)^{113,114} and the SCRPM mechanism^{115–118} with the latter being particularly active in confined environments displaying high viscosity.

CIDEP has been frequently utilized as a tool to establish photophysical processes and details of molecular arrangements in the solid state with many contributions in systems with charge-separated states (e. g., photosynthesis¹¹⁹).

In terms of the instrumental effort, commercial EPR spectrometers have to be modified to allow the acquisition of EPR spectra in the nanosecond–microsecond time domain. The microwave bridge has to be adjusted (amplifier), the spectral acquisition has to be synchronized with the source triggering the generation of radicals, and the transfer of data has to be interfaced between the components of the spectrometer. Such experiments can be performed on spectrometers based on a conventional continuous wave (cw-X) band EPR spectrometer, at W-band (10 MHz, high field), or pulsed spectrometers.

Here, we will restrict ourselves to examples contributing to the understanding of chemical reactivity

Figure 12 The triplet mechanism of CIDEP.

of (organic) radicals taking advantage of the substantial time resolution of CIDEP (radical lifetimes in the 50 ns to μ s region) and of the increased sensitivity caused by the “physical” mechanisms sketched above.

6.1 CIDEP and Radical Polymerization

With the general principle of the photolytic generation of radicals, and follow-up of formation of carbon-centered radicals and reactions on a nanosecond–microsecond timescale, photoinduced radical polymerization is an ideal paradigm for demonstrating the power of CIDEP. Accordingly this technique will be illustrated by choosing examples from photoinitiators.

Photolysis of aliphatic or aromatic ketones often leads to the homolytic cleavage of the bond in α -position to the keto group. This has been utilized to produce biradicals¹²⁰ starting with cyclic ketones. Hydrogen abstraction reactions by excited states of carbonyl compound can as well be utilized as starting reactions to observe radicals based on acrylates at a short timescale.^{121,122}

Many (also commercially applied) initiators for radical polymerization rely on such α -cleavage reactions (Section 3.2)¹²³; with the lifetime of the initiating species being short, CIDEP is the method of choice to observe the primary radicals. An example for a bisacylphosphineoxide is shown in Figure 13. The three signals stem from two

radicals: the central line represents an unresolved EPR spectrum of the 2,4,6-trimethylbenzoyl radical and the two outer lines are due to the P-centered substituted phosphinoyl radical (which also do not show additional resolution here). The dominating interaction here is that between the unpaired electron and the ^{31}P nucleus, which leads to the considerable isotropic HFCC of 25.8 mT (the distance between the two outermost lines). In contrast to steady-state EPR, here the two lines representing the ^{31}P coupling do *not* possess identical intensities. This reveals the presence of both, TM *and* RPM, being responsible for the polarization. Accordingly, particularly when these mechanisms contribute to the line intensities, the decay of the EPR signal does not represent the lifetime of the radical.

When a monomer is added to the reaction solution, the spectra undergo significant alterations. This is displayed in Figure 14 for a mixture of phenylbis(2,4,6-trimethylbenzoyl)phosphine oxide and butyl acrylate in toluene. Immediately after photolysis, the three lines corresponding to those shown in Figure 12 are visible. After circa 300 ns, additional signals start to grow in the center of the spectrum. They unambiguously stem from growing-chain radicals of the polymer at a very early stage (addition of a first acrylate to the initiating radicals). Then, at 700–800 ns the signals of the initiating radicals disappear, and also the intensity of the central signal stemming from the C-centered radicals CP and CC (Scheme 8) starts to fade in the spectrum although this type of radicals is

Figure 13 CIDEF spectrum obtained after laser-flash photolysis of phenylbis(2,4,6-trimethylbenzoyl)phosphine oxide. [Reproduced with permission from I. Gatlik, PhD thesis, Univ. Basel, 2001.]

Figure 14 CIDEF spectra of phenylbis(2,4,6-trimethylbenzoyl)phosphine oxide in the presence of butyl acrylate.

much longer lived. The reason for this observation is that only radicals carrying a substantial amount of polarization are detectable by this technique. Thus, when the polarization created by TM and RPM in the initial stage relaxes, subsequently formed radicals become “invisible.”

Often, the central signals in X-band EPR spectra overlap, and an unambiguous analysis of the signals is impaired. A helpful development is the design of high-field (W-band) time-resolved EPR spectrometers,¹²⁴ which (analogous to the extension of the chemical shift resolution corresponding to the g -factor scale in

EPR) enhances the resolution between EPR signals of different radicals. The power of this approach is demonstrated in Figure 15, which shows the photolysis of 1-(4-methylthio)phenyl-2-(4-morpholinyl)-2-phenylpent-4-en-1-one. Here, the 4-methylthiobenzoyl (b in Figure 14) and the corresponding α -amino carbon-centered radical (c in Figure 15) are formed.¹²⁵ While the X-band EPR shows two overlapping signals, they are well separated in the W-band spectrum substantially simplifying analysis (another feature is the different polarization of the signals which

Scheme 8 Radicals observed during the first steps of radical polymerization.

Figure 15 (a) X- and (b) W-band time-resolved EPR spectra of 1-(4-methylthio)phenyl-2-(4-morpholinyl)-2-phenylpent-4-en-1-one.

is due to a substantial contribution of Boltzmann distribution¹²⁴).

With the structures of short-lived radicals and the observation of growing polymer chains being established, it is tempting to utilize CIDEP for measuring rate constants for radical reactions, in particular, the

addition of a monomer to the initiating radical.¹²⁶ This is more valuable since often the short-lived radicals can unambiguously be identified by CIDEP, but are hardly detectable by optical techniques because either they have very low extinction coefficients as their absorptions are masked by reaction products or the bands are too far in the UV region. As shown above, CIDEP has the shortcoming that the polarization mechanisms cause the situation where the decay curves do not generally represent chemical lifetimes. Bartels *et al.*, have shown how to circumvent this obstacle^{127,128} by using the linewidth of the CIDEP signals (indicating the lifetime of the radical—lifetime broadening). This principle was shown to work well with more complex reactions followed by cw and FT-EPR.^{125, 129–131} With this approach, the addition constants of several monomers to initiating radicals could be determined.

6.2 CIDEP Radical Ions and Follow-Up Products

Conversions of peptides and DNA residues on oxidative stress are of principal interest. Such conditions can be modeled by reacting the substrates with oxidants like 9,10-anthraquinone-2,6-disulfonic acid (AQDS). This oxidant is well soluble in water, but it must be taken into account that its reactivity is pH dependent.

When AQDS is reacted with thymine and the reaction is followed by FT-EPR CIDEP spectra, the formation of the thymine-1-yl radical and an AQDS-based radical (depending on pH) are detected (Scheme 9)¹³²; accordingly under the given

Scheme 9 Reactivity of thymine and 1-methylthymine upon photoinduced reaction with AQDS as established with FT-CIDEP.

experimental conditions, deprotonation of the primary thymine radical cation is very rapid. With 1-methylthymine, however, the analogous reaction leads to the detection of the corresponding radical cation together with deprotonated isomers. In the presence of phosphate buffer and phosphoric acid, a phosphate adds to the 6-position of thymine (Scheme 9).¹³³ In a similar way, the formation of radicals from cyclic dipeptides was followed.¹³⁴ A summary of organic radicals detected via CIDEP can be found in Ref. 135.

7 CONCLUSIONS

The results presented here demonstrate that short-lived paramagnetic species, preferentially (organic) radicals can be very well distinguished by CIDNP and CIDEP. Both techniques take advantage of RP phenomena and transitions between spin-correlated triplet and singlet domains. While CIDNP provides information on reaction products and offers knowledge on the reaction pathways and intermediates, which led to these products, CIDEP characterizes the initially formed radicals. However, care must be taken for the interpretation of these results since the signals depend on several (photo)physical and magnetic phenomena.

The TR-CIDNP technique is very suitable for characterizing short-lived paramagnetic reaction intermediates, whereas it has to be emphasized that only the polarization observed within the first microsecond after the photoexcitation arises solely

from recombination of geminate RPs. Thus, any attempts to get quantitative information about the geminate evolution of radicals from CIDNP spectra detected at continuous irradiation of the sample are fault-prone. Important consequences for CIDNP of protein residues are in particular not only geminate factors, such as surface accessibility that determines the CIDNP amplitude, but also effects of neighboring groups, for example, of N versus C terminal, which have to be taken into account. As it has been demonstrated, aromatic amino acid residues give CIDNP, and at the N-terminus other residues, such as Gly, also become polarized. Moreover, the protonation state of the diamagnetic and paramagnetic species plays a major role. The direct application of the CIDNP method to complex peptides may lead to erroneous conclusions; therefore, systematic studies on peptides of increasing complexity are necessary in the first place.

Time-resolved measurements allow to separate primary and secondary reaction stages and to determine the reaction rates as well as the paramagnetic nuclear relaxation times at the radical stage. Because of the high spectral resolution, site-specific information on the spin density distribution in the radicals was achieved. From these data, information about the structure of the radicals and the way of their formation was obtained. At ambient conditions, in aqueous solutions these species are too short-lived to be registered by EPR. On the other hand, they do not have an absorption band to be detected by optical spectroscopy. However, the time-resolved and field-dependent CIDNP methods at high field

allowed for the identification of the radicals and determination of their structure.

The identification of radicals via CIDEP proceeds in a straightforward way analogous to standard CW-EPR since the hyperfine patterns are constructed in the same way. However the CIDEP signal intensities are substantially controlled by TM and RPM and, accordingly, do not reflect steady-state conditions. Thus, the intensity patterns of time-resolved EPR spectra in the nanosecond–microsecond region present intensities which do not simply reflect radical concentrations. These mechanisms also hamper a direct kinetic analysis. Nevertheless, kinetic analysis is feasible by line-shape analysis (or direct measurement of T_2).

In a nutshell, CIDNP and CIDEP provide an advantageous way for a straightforward and highly sensitive detection of short-lived radicals. Moreover, the photophysical details can be deduced from the spectra. The possibilities of using these techniques to answer questions in the field of chemical reactions involving homolytic bond cleavage, atom abstraction, or electron transfer are immense. Although this methodology has been developing over decades, its scope is, by far, underestimated.

Matrix Isolation of Radicals

Artur Mardyukov and Wolfram Sander

Lehrstuhl für Organische Chemie II, Ruhr-Universität Bochum, Bochum, Germany

1 INTRODUCTION

1.1 Matrix Isolation

Since its introduction almost half century ago, matrix isolation spectroscopy has been one of the most important tools for the characterization of free radicals.^{1–4} In 1954, Pimentel *et al.* published their studies of trapping unstable species in frozen inert gases.⁵ Argon, xenon, and nitrogen were used as inert matrices to stabilize molecules that are otherwise not isolable, either because they are highly reactive (dimerize or react with other molecules) or because they have a high tendency for aggregation (e. g., formation of hydrogen bonds). Although frozen organic solvents (organic glasses) had been used before for the stabilization of reactive molecules, the introduction of frozen inert gases as medium was the important step forward that allowed the isolation and spectroscopic characterization of even the most reactive free radicals. Under conditions of matrix isolation, radicals are kinetically stabilized by using cryogenic temperatures (below 20 K) and by immobilization of the radicals (preventing diffusion) in a chemically inert environment. As a matter of fact, immobilization is so complete that even the rotation of molecules is prevented (with the exception of water and other similar very small molecules that show a hindered rotation in matrices). Thus, bimolecular reactions that require the diffusion of the components are completely inhibited and unimolecular reactions are extremely slowed down by the low temperatures.

Rearrangements are only observed if the activation barriers are less than approximately 2 kcal mol^{−1} or if tunneling takes place.

Typical conditions for matrix isolation are high dilution (1:500–1:2000 matrix ratio), very low temperatures (3–10 K), and argon, neon, or nitrogen as inert matrix (Figure 1). Argon and nitrogen can be used between 10 and 30 K, whereas neon matrices require temperatures below 6 K. Matrix isolation is basically a preparative technique, and the goal is to obtain high yields of the reactive intermediate. For the synthesis of radicals, there are two basic techniques available: either a suitable photolabile precursor is matrix-isolated and the radical is formed in a subsequent photolytical step, or the radical is produced in the gas phase via flash vacuum pyrolysis (FVP), and the pyrolysis products are subsequently trapped with a large excess of inert gas on top of a cold spectroscopic window. Other techniques, such as laser ablation^{6,7} or microwave discharge,^{8,9} are less generally used.

The photolysis of matrix-isolated precursors is the technique most frequently used for the synthesis of matrix-isolated radicals; however, this method has some severe drawbacks. In a typical photochemical synthesis, singlet radical pairs are produced by the cleavage of a covalent bond in the photochemically excited precursor. In the gas phase or in solution, these radicals might diffuse apart, form triplet pairs via intersystem crossing (ISC) or isolated radicals. In the solid matrix, however, diffusion is inhibited and the radical pair is trapped in a matrix cage. In many cases, this results in a rapid recombination back to the precursor. Thus, iodobenzene can be

Figure 1 Phenyl radical trapped in argon.

used as photochemical precursor of phenyl radicals in the gas phase, whereas under the conditions of matrix isolation, only traces of radicals are formed owing to the rapid recombination of the phenyl radical and the iodo atom. The yields of radicals formed by matrix photolysis depend on the precursor, the matrix material, and the temperature. Therefore, some precursors give reasonable yields of radicals in argon at 10 K, whereas others require temperatures as low as 3 K or neon matrices.^{10–13} Unfortunately, this is not predictable and a series of experiments is necessary to optimize the photolysis conditions.

To circumvent these problems, diacylperoxides have been used as photochemical precursors of radicals.¹⁴ Cleavage of the O–O bond results in the formation of highly labile acyloxy radicals, which readily split off CO₂ under the formation of a radical pair separated by two molecules of CO₂. Owing to the photolysis, the initially formed radicals are vibrationally excited, which might lead to local heating of the matrix and subsequent diffusion and recombination processes. Again, the yields of radicals are unpredictable and highly dependent on the experimental conditions.

Another disadvantage of the photolytical synthesis of matrix-isolated radicals is that they, if formed at all, are in close proximity to other products of the photolysis. This results in intermolecular interactions that might lead to spectral shifts and line broadening. Annealing of these matrices at higher temperatures (see below) induces diffusion and in most cases results in recombination of the radical pair.

Figure 2 Cryostat combined with a pulsed hyperthermal nozzle. After the expansion into the high vacuum system, the molecular beam is trapped on a cold spectroscopic window.

A different technique to generate free radicals, which avoids these problems, is the FVP, followed by trapping of the pyrolysis products in an inert matrix. Under these conditions, the radicals are formed in the gas phase and trapped in individual matrix cages. Therefore, radical recombination is unlikely as long as the matrix is highly diluted and diffusion is prevented. A problem of this technique is that the energy is transferred to the precursor molecule by collisions with the wall of the hot pyrolysis tube. This frequently leads to unwanted decompositions and side reactions, resulting in low yields of radicals. To overcome this problem, the precursor has to be carefully selected.

Alternatively, a pulsed hyperthermal nozzle can be used to produce the radicals in a supersonic jet.^{2,15,16} In this case, the energy is transferred to the precursor via collisions with a hot inert gas, which is much cleaner than wall collisions. In a supersonic expansion, the radicals are already cooled down and subsequently trapped with the inert gas (most frequently argon) on a cold spectroscopic window to form the matrix. Prerequisite for this method is that the radical precursor has a rather high vacuum pressure to seed the inert gas. For a number of small radicals, very clean spectra could be obtained this way (Figure 2).^{2,17,18}

1.2 Spectroscopy of Matrix-Isolated Radicals

The most important spectroscopic methods used for the characterization of matrix-isolated radicals are electron paramagnetic resonance (EPR) and infrared

(IR) spectroscopy. Other methods frequently used are UV–vis and fluorescence spectroscopies, but by far the most useful method for the characterization of matrix-isolated species is IR spectroscopy. The absence of molecular rotations and the weakly interacting environment results in well-resolved, narrow bands of high intensity. Even in complex mixtures, IR bands of the individual molecules are in most cases well separated and can be directly compared to gas phase spectra or quantum chemical calculations (which in most cases are used to calculate gas phase IR spectra). Neon is the least interacting matrix host, and molecular vibrations of molecules isolated in neon show only small deviations from the gas phase values (in average less than 1 cm^{-1}). Argon is most frequently used as matrix since it requires less sophisticated cryostats (10 K instead of 4 K for neon). The deviation of IR frequencies compared to the gas phase is significantly larger here, but on average still less than 2 cm^{-1} (Figure 3).⁸

To obtain IR spectra, the matrix is deposited either on a cold spectroscopic window such as CsI that is positioned in the IR beam or on a reflecting metallic mirror to measure in reflectance. In the early days of matrix spectroscopy, the most difficult task was to assign the spectra and to identify reactive species such as radicals in the matrix. The synthesis of the same radical from chemically very different precursors is one method to become confident about the identification. Extensive

isotopic labeling is another important tool for the assignment of species. Nevertheless, since many of the reactive species isolated in matrices were completely unprecedented, many early assignments were only tentative and some assignments later had to be corrected. The development of powerful quantum chemical methods (density functional theory (DFT) and *ab initio*) for the calculation of IR spectra was a major step forward for IR matrix spectroscopy and largely improved the assignments of new and unusual species.

An interesting method that has been successfully used in some cases to gain information on the symmetry of IR or UV–vis transitions is based on the complete immobilization, including rotation, of molecules in inert gas matrices at very low temperatures.^{19,20} Since rotations are inhibited in matrices, the distribution of orientations of trapped molecules is random. If these matrices are irradiated with linear polarized light, molecules with their transition moment vectors oriented closely to the direction of the E-vector of the irradiating light will undergo faster photolysis than molecules oriented in other directions. Partial photolysis therefore leads to an orientation of both the remaining precursor and the product formed. This results in IR or UV–vis dichroism if the spectra are recorded using a polarized IR or UV–vis beam, respectively. The analysis of these spectra allows to obtain information on the symmetry and in some cases even on the geometry of the molecules.

EPR spectroscopy is the other important tool to characterize matrix-isolated radicals. The method is very sensitive and specific to paramagnetic species. This allows detection of very low concentrations of radicals. Thus, frequent by-products in pyrolysis reactions are hydrogen atoms or methyl radicals, which are easily detected by EPR spectroscopy. The high sensitivity can also be a disadvantage, since minor paramagnetic side products might result in large signals, whereas major diamagnetic products are not observed at all. In most instances, EPR spectra of radicals were measured in organic glasses at $4\text{--}77\text{ K}$. These are easily prepared by cooling solutions of the precursor in a suitable solvent that forms glasses upon freezing. However, these glasses are strongly interacting with the solute and in many cases react with the radicals and other highly reactive species. Thus, matrix EPR spectroscopy is a better choice, although technically more demanding. For these experiments, the matrix is deposited on

Figure 3 Deviation of IR frequencies measured in neon and argon, respectively, compared to gas phase values. [M. E. Jacox, *Chem. Soc. Rev.*, 2002, **31**, 108. Reproduced by permission of The Royal Society of Chemistry. <http://dx.doi.org/10.1039/B102907J>.]

Figure 4 Cryostat with attached copper rod and quartz tube for EPR spectroscopy.

top of a copper or sapphire rod, which is positioned inside a quartz tube in a high vacuum system (Figure 4). This quartz tube is then inserted into the microwave cavity of the EPR spectrometer.

1.3 Reactions of Matrix-Isolated Radicals

Matrices are well suited to isolate and characterize radicals. Irradiation of matrix-isolated radicals with visible or UV light in many cases results in rearrangements or fragmentations. These might be true photochemical reactions or hot ground-state reactions induced by local heating via internal conversion from excited states. In some instances, xenon exciplexes were successfully used to induce thermal reactions in cryogenic matrices.²¹ However, this technique requires that the precursor does not absorb the light required for the formation of the exciplexes, and has not found many applications.

Bimolecular reactions in matrices require the diffusion of the components in the solid state. Small molecules such as O₂, CO, or CO₂ diffuse rapidly if the matrix is annealed at a temperature of about 30–50% of its melting point. For argon, this is at 30–35 K and for neon, this is already at 5–6 K. At these temperatures, bimolecular reactions can be monitored directly by spectroscopy. Prerequisite for a bimolecular reaction to take place at these low temperatures is an extremely low or absent activation barrier, such as for many radical recombinations. This is the reason why bimolecular reactions

other than recombination of the radical pair to form back the precursor molecule are rarely observed if the radical has been produced photochemically. The best conditions to observe bimolecular reactions of matrix-isolated radicals are synthesis of the radicals via FVP and subsequent trapping in argon or nitrogen doped with 0.5–2% of the second reactant at 3–10 K. If the radicals are trapped in matrix cages that contain a reactive molecule (e. g., molecular oxygen), the reaction product is formed directly after deposition. At concentrations between 0.5% and 2%, still enough radicals are trapped that do not directly react with the added reagent. Annealing of these matrices at 25–35 K results in bimolecular reactions induced by diffusion.

In this article, we focus on matrix-isolated radicals of relevance to organic chemistry. Atoms and small diatomic radicals such as HO[•] have been excluded as also mainly inorganic radicals and EPR studies in organic glasses. Some of these systems are covered in a recent, highly recommended review.²² Most of the organic radicals described here are of fundamental importance and have been characterized by both IR and EPR spectroscopy. This provides detailed insight into the electronic structure, spin distribution, and geometry of these radicals. A step further is investigations of uni- and bimolecular reactions in matrices, which give important information about radical reactivity and the primary reaction products. These data are included in the article wherever they are available.

2 ALKYL RADICALS

2.1 Methyl Radical

The methyl radical is a highly reactive intermediate of fundamental importance to chemistry,²³ which plays a key role in atmospheric chemistry²⁴ and combustion processes.²⁵ Therefore, methyl radical has been investigated in a large number of studies using a variety of spectroscopic methods such as EPR,^{26,27} IR,²⁸ or UV–vis spectroscopy in combination with the matrix-isolation technique. A major question that has been addressed by many spectroscopic studies concerned the structure of CH₃[•], in particular whether or not it is a planar species or pyramidal with a low inversion barrier. This question was settled by a gas phase

microwave study,²⁹ which, in accordance with quantum chemical calculations,¹⁴ indicates a planar structure with D_{3h} symmetry. Thus, the methyl radical is described best as a π -radical with the unpaired electron in the carbon p orbital perpendicular to the CH bond.

The matrix isolation of $\text{CH}_3^\bullet$ was pioneered by Milligan and Jacox in 1967.³⁰ Vacuum UV photolysis of methane, matrix-isolated in argon or nitrogen at 14 K, results in the formation of the methyl radical with a UV absorption at 150.3 nm, in agreement with the gas phase absorption that had been previously reported by Herzberg and Shoosmith,³¹ and a prominent IR absorption at 611 cm^{-1} . The latter band was assigned to the CH out-of-plane deformation mode, which was confirmed by deuterium and ^{13}C isotopic labeling that resulted in the predicted isotopic shifts.³⁰ As expected, the harsh irradiation conditions do not selectively produce $\text{CH}_3^\bullet$, but rather a complex reaction mixture that also contains CH, C_2 , C_3 , and C_2H_2 . Although not directly observed, the formation of CH_2N_2 in nitrogen matrices indicates that CH_2 is also present. Annealing of matrices containing $\text{CH}_3^\bullet$ results in the disappearance of this species via bimolecular reactions (e. g., with hydrogen atoms to give back CH_4), which is indicative of its reactive nature. To record more complete spectra of $\text{CH}_3^\bullet$ and to investigate its chemistry under the conditions of matrix isolation, more suitable precursors and higher yields of the radical were clearly necessary.

Methyl iodide and dimethyl mercury were used as precursors of $\text{CH}_3^\bullet$ and $\text{CD}_3^\bullet$ using FVP with subsequent trapping of the products in neon at 4 K (Scheme 1). Three IR active bands were observed, and the D_{3h} structure was confirmed by these experiments.³² Another interesting method for the generation of matrix-isolated $\text{CH}_3^\bullet$ is the abstraction of H atoms from CH_4 with fluorine atoms.²⁸ Fluorine

atoms are generated by microwave discharge of an Ar/ CF_4 or Ar/ NF_3 mixture. If the Ar/F mixture is codeposited with CH_4 to form an argon matrix, HF and $\text{CH}_3^\bullet$ are detected by IR spectroscopy (1). Additional sets of vibrational bands were assigned to the $\text{CH}_3\text{F}\cdots\text{HF}$ and $\text{CH}_3^\bullet\cdots\text{HF}$ weakly bound complexes.²⁸ Johnson and Andrews³³ photolyzed the $\text{CH}_4\cdots\text{F}_2$ van der Waals complex in argon to obtain the $\text{CH}_3^\bullet\cdots\text{HF}$ complex with a prominent HF stretching mode at 3764 cm^{-1} .

Therefore, matrix isolation not only allows to generate and characterize the methyl radical but also to obtain weakly bound complexes of the radicals. An interesting question is whether complexation leads to pyramidalization of $\text{CH}_3^\bullet$. Indeed, the hyperfine constant determined from electron spin resonance (EPR) experiments indicates C_{3v} symmetry for the $\text{CH}_3^\bullet\cdots\text{HF}$ complex, in agreement with *ab initio* calculations at the UMP4/6-311(d,p)//UMP2/6-311(d) level of theory.^{34,35}

The D_{3h} symmetry of $\text{CH}_3^\bullet$ implies that the IR active modes with E' , A_1' , and A_2' symmetry are Raman inactive and similarly the Raman modes are IR inactive. In accordance with this, the three IR active frequencies are found at $\nu_4 = 617\text{ cm}^{-1}$ (A_2'), $\nu_1 = 3162\text{ cm}^{-1}$ (E'), and $\nu_2 = 1396\text{ cm}^{-1}$ (E'') (Figure 5).¹⁴

The EPR spectra of the methyl radical trapped in various matrices have been investigated in detail. In solid N_2 , CO, and CO_2 , the EPR spectra show axial anisotropy, which indicates a free rotation about the C_3 axis.²⁶ In Ar, an isotropic EPR spectrum was

Scheme 1 Reaction channels for the synthesis of methyl radical.

Figure 5 Normal mode displacement diagrams for the methyl radical.

observed above 20 K, whereas in Kr, the spectrum is isotropic throughout the whole temperature range.²⁷ This suggests that below 20 K in argon, CH₃[•] is not rotating. In methanol glass, the EPR spectrum shows forbidden lines as satellites as a result of dipolar coupling of the unpaired electron with protons of neighboring methanol molecules.³⁶

The reaction of CH₃[•] with molecular oxygen produces the methyl peroxy radical (2), an important reactive intermediate in the oxidation of methane³⁷ that plays a major role in the oxidation of NO to NO₂. This process is of large relevance to stratospheric chemistry, since NO₂ is the direct precursor of ozone smog and a major driving force in urban air pollution (3–6).^{38,39}

Of relevance to atmospheric chemistry is also the reaction of the methyl radical with ozone (7), which has been the subject of several direct⁴⁰ and indirect studies.⁴¹ Albaladejo *et al.* determined the rate constant for the reaction (7) to be $9.68 \pm 1 \times 10^{-14} \text{ cm}^3 \text{ molecule}^{-1} \text{ s}^{-1}$. The methoxyl radical (CH₃O[•]) formed in this reaction was detected by laser-induced fluorescence (LIF) spectroscopy.⁴²

The methyl peroxy radical (CH₃OO[•]) was isolated in cryogenic matrices by co-depositing pulses of methyl radicals produced by pyrolysis of azomethane and pulses of O₂/Ar.⁴³ Ten of the 12 fundamental IR absorptions were observed and the symmetries (a' or a'') were determined via photoorientation of the trapped species. According to these experiments, the methyl peroxy radical is planar with 12 vibrational modes that are all IR active (Table 1).⁴³

According to electron affinity and gas phase acidity measurements⁴⁴ in combination with *ab initio* calculations,⁴⁵ the heat of formation $\Delta_f H_{298}$ of the methyl peroxy radical (CH₃OO[•]) was determined to be $4.8 \pm 1.2 \text{ kcal mol}^{-1}$. From that follows a heat of reaction $\Delta_{\text{rxn}} H_{298}$ for the direct reaction of the methyl radical with molecular oxygen of $-30.1 \pm 1.2 \text{ kcal mol}^{-1}$.

The electronic structure of CH₃OO[•] in its ground state is X ²A'' with a low-lying A ²A'' excited state in the near-IR.⁴⁶ The electronic spectrum shows a broad transition at 250 nm attributed to the excitation to the B ²A'' state.³⁹

2.2 Ethyl Radical

The ethyl radical has been extensively studied over the past three decades, both experimentally⁴⁷ and theoretically.⁴⁸ The first high-resolution IR spectrum of CH₃CH₂[•] in the gas phase was obtained by Johnson and Sears,^{49,50} showing a band at 528 cm^{-1} attributed to the out-of-plane vibration at the CH₂ radical center. A barrier of about 20 cm^{-1} was determined for the rotation about the CC bond. The almost free internal rotation has been later confirmed by high-level *ab initio* calculations. Davis *et al.*⁵¹ reported the rotationally resolved spectrum of the CH stretching region of the jet-cooled ethyl radical. The strong coupling between the CH₂ and CC torsional modes was attributed to open-shell hyperconjugation between the singly occupied p orbital at the radical center and the β-CH bond in the methyl group. This stabilizing interaction results in a shortening of the CC bond and elongation of the CH bond compared to ethane.¹⁴

The C_s symmetrical ethyl radical possesses 15 vibrational modes, 9 of A' symmetry and 6 of A'' symmetry, which are all Raman and IR active.¹⁴ The IR spectrum of the ethyl radical in an argon matrix was reported by Pacansky *et al.* The radical was generated by irradiation of dipropionyl peroxide in high yield (8).^{52,53} A quantitative assignment of the spectrum was obtained by comparison with calculated spectra at the unrestricted Hartree–Fock (UHF) and UMP2/6-311G(d,p) levels of theory.^{14,54} The matrix IR spectrum of $CH_3CH_2\cdot$ shows a strong CH stretching vibration at 2840 cm^{-1} , which is unusually low in frequency, and assigned to the CH stretching mode of the β -CH bond. The low frequency of the CH stretching vibration was also observed in the partially deuterated ethyl radical. The redshift indicates the weakening of the β -CH bonds in alkyl radicals by hyperconjugation.⁵⁵

The EPR spectrum of the ethyl radical was observed after γ -radiolysis of ethane⁵⁶ or ethyl halides at 77 K,⁵⁷ UV photolysis of ethyl alcohol at 77 K,⁵⁸ or photolysis of ethyliodide in argon at 4 K.⁵⁹ Owing to the broadening of the EPR spectra by dipolar interactions, it was not possible to determine the anisotropic hyperfine couplings. McDowell *et al.*⁶⁰ obtained the EPR spectrum of the ethyl radical in an argon matrix after UV photolysis of a mixture of ethane and HI. The lineshape analysis allowed determination of the anisotropic hyperfine interaction parameters for the α and β protons as well as the g -values ($A^\alpha = 19.4 \pm 0.5$ G, $A^\alpha = 29.6 \pm 0.5$ G, $A^\beta = 25.9 \pm 0.5$ G, $A^\beta = 28.7 \pm 0.5$ G, $g_{\text{av}} = 2.0023 \pm 0.0003$, $\Delta g = g_{||} - g_{\perp} \leq 0.0003$).

A variety of spectroscopic techniques including UV absorption spectroscopy,⁶¹ flash photolysis/time-resolved UV spectroscopy,^{62,63}

mass spectrometry,⁶⁴ pulse radiolysis,⁶⁵ and recently, near-IR cavity ring-down spectroscopy were used to obtain kinetic and mechanistic data of the reaction of the ethyl radical with molecular oxygen (9).⁶⁶ Snelson's laboratory has reported the matrix IR spectra of several alkylperoxy radicals prepared by $[R^\cdot + O_2]$ recombination reactions. Chettur and Snelson⁶⁷ pyrolyzed azoethane to produce the ethyl radical that was subsequently deposited in a mixture of oxygen and argon at 10 K. Mode assignments were based on the frequency shifts using isotopically labeled $^{18}O_2$. The OO stretching mode at 1112 cm^{-1} shows the expected large redshift of 47 cm^{-1} when $^{18}O_2$ was used.

2.3 *n*-Propyl and Isopropyl Radicals

The matrix IR spectrum of the isopropyl radical was reported for the first time by Pacansky and Counfal in 1980 (Scheme 2).⁶⁸ Irradiation of diisobutyl peroxide in an argon matrix with UV light produces the isopropyl radical in good yield. Further irradiation with shorter wavelength UV light leads to isobutyric ester, propylene, and isopropyl isobutyrate (Scheme 3). The formation of the latter product is explained by the reaction of the excited radical with CO_2 . The IR spectrum reveals that more than one conformer of the isopropyl radical is trapped in the matrix. According to quantum chemical calculations, the isopropyl radical is nonplanar at the radical center and shows C_s symmetry with the α -CH bond lying in the plane of symmetry and the two methyl groups being symmetrical to this plane. The nonplanar geometry at the radical center introduces some s character into the carbon p orbital of the unpaired electron, and the geometry acquires a pyramidal structure similar to ammonia.¹⁴ Pacansky *et al.* located seven different conformers of the isopropyl radical of very

Scheme 2 Generation and thermal reactions of *n*-propyl radical in argon matrix.

Scheme 3 Photochemistry of diisobutyryl peroxide in an argon matrix.

similar energy, which differ mainly by rotation of the methyl groups.^{69,70}

The isopropyl radical $i\text{-C}_3\text{H}_7\cdot$ was synthesized by pyrolysis of bis(1-methylethyl)diazene and subsequently trapped in solid argon.⁷¹ The radical shows a characteristic out-of-plane bending mode at 374 cm^{-1} . Irradiation of the isopropyl radical results in its rearrangement to the n -propyl radical with bands at 523, 1035, 3028, and 3118 cm^{-1} . Upon annealing of the matrix at 40 K, the n -propyl radical dimerizes to n -hexane.

The isopropyl peroxy radical was synthesized by the reaction of the isopropyl radical with molecular oxygen in an argon matrix (10).⁷¹ The nonlinear COO group in this radicals results in a lowering of the symmetry to either C_1 or C_s symmetry with a total of 30 IR active frequencies. The $\nu(\text{OO})$ stretching mode shows the expected pronounced redshift from 1101 to 1059 cm^{-1} when $^{18}\text{O}_2$ is used.

The n -propyl radical was also directly synthesized and characterized in argon matrices.^{72,73} UV photolysis of dibutyryl peroxide produces the n -propyl radical and CO. Annealing of the matrix to allow diffusion of the n -propyl radical results in its dimerization to n -hexane and disproportionation to n -propane and propene.

3 UNSATURATED RADICALS

3.1 Ethynyl Radical

The ethynyl radical, $\text{C}_2\text{H}\cdot$, is an unsaturated aliphatic radical that plays an important role in combustion chemistry,⁷⁴ as a key intermediate in the formation of polyenes in the atmospheres of planets^{75,76} and as a constituent of interstellar clouds.^{77,78} The bond dissociation energy DH_{298}

of the CH bond of acetylene has been determined by negative ion mass spectroscopy and photoelectron spectroscopy to be $133.3 \pm 0.3\text{ kcal mol}^{-1}$, and the heat of formation $\Delta_f H_{298}$ to $135.6 \pm 0.2\text{ kcal mol}^{-1}$.^{44,79}

A high-resolution gas phase spectrum was obtained for the lowest rotational transition in the $X^2\Sigma^+$ electronic ground state of $\text{C}_2\text{H}\cdot$.⁷⁷ The very complex rotational spectrum of $\text{C}_2\text{H}\cdot$ was obtained at millimeter and submillimeter wavelengths in the vibrational ground state^{80–82} and in the lowest bending vibrational level.⁸³ The complexity of the spectrum arises from the vibronic coupling of the bending and CC stretching vibrations in the $X^2\Sigma^+$ ground state with the low-lying $A^2\Pi$ state.^{84–86} The energy between the $A^2\Pi$ and $X^2\Sigma^+$ states was determined to be about 3700 cm^{-1} .⁸⁷ Laser magnetic resonance (LMR) spectroscopy in combination with quantum chemical calculations was used to determine the lowest vibronic state of the $A^2\Pi$ state.^{88–90} Carrick *et al.*⁹¹ used high-resolution color center laser spectroscopy to assign several bands of the $A^2\Pi \leftarrow X^2\Sigma^+$ system in the region $3600\text{--}4200\text{ cm}^{-1}$. Time-resolved absorption spectroscopy allowed to assign a UV absorption at 243 nm to an electronic transition of $\text{C}_2\text{H}\cdot$.⁹²

Milligan *et al.*⁹³ reported the isolation and IR spectroscopic characterization of $\text{C}_2\text{H}\cdot$ in solid argon. The radical was generated by discharge in $\text{C}_2\text{H}_2/\text{Ar}$ mixtures and trapped on a spectroscopic window at 14 K. The complicated spectrum contains more than 50 transitions between 3000 and 8000 cm^{-1} arising from a conical intersection between the Σ^+ and Π states.⁸⁶ A band at 1848 cm^{-1} was assigned to the $\text{C}\equiv\text{C}$ stretching mode ν_3 of $\text{C}_2\text{H}\cdot$, which was confirmed by isotopic substitution studies, and a band at 3611 cm^{-1} was

Scheme 4 Photochemistry of acetylene.

attributed to the CH stretching mode ν_1 .⁹⁴ ^{13}C substitution allowed to assign the band at 3610 cm^{-1} to a combination vibration ($\nu_1 + \nu_2$ or $\nu_1 + 2\nu_2$) and in addition bands at 2104 and 258 cm^{-1} to the $\nu_2 + \nu_3$ and ν_2 bending modes.⁹⁵ Wu and Cheng⁹⁶ generated $\text{C}_2\text{H}\cdot$ by vacuum UV photolysis of acetylene in solid neon using synchrotron irradiation at 185, 171, 130, and 114 nm and found that in particular 171-nm irradiation is efficient to produce the $\text{C}_2\text{H}\cdot$ radical (Scheme 4). Although the major photoproduct formed under these conditions is $\text{C}_2\text{H}\cdot$, other photoproducts observed are C_2H_3 , C_4 , C_4H , C_4H_2 , C_6 , and C_8H_2 . The high yields of $\text{C}_2\text{H}\cdot$ obtained in these experiments allowed to reassign the CH stretching mode ν_1 at 3292.3 cm^{-1} (2536.7 cm^{-1} in $\text{C}_2\text{D}\cdot$).⁹⁶

3.2 Vinyl Radical

The vinyl radical $\text{C}_2\text{H}_3\cdot$ plays a role in combustion and atmospheric chemistry, and therefore has been subject to a number of experimental and theoretical studies.^{74,97} The vinyl radical is typically produced by H-atom abstraction from ethylene. The CH bond dissociation energy DH_{298} of ethylene was determined to be $110.7 \pm 0.6\text{ kcal mol}^{-1}$, and the heat of formation $\Delta_f H_{298}$ of the vinyl radical was determined to be $71.1 \pm 0.6\text{ kcal mol}^{-1}$.^{44,79}

The vinyl radical is a σ -type radical with an X^2A' electronic ground state.^{97,98} Electron spin resonance (EPR) studies indicate that the vinyl radical is essentially planar and the unpaired electron occupies an sp^2 hybrid orbital.^{99,100} The structure and electronic properties of the vinyl radical were investigated at various levels of theory.^{97,98,101,102}

The electronic absorption spectrum of $\text{C}_2\text{H}_3\cdot$ reported by Hunziker *et al.* shows an absorption at

499.5 nm assigned to the $^2A'' \leftarrow ^2A'$ transition.¹⁰³ The UV spectrum was later also observed by cavity ring-down spectroscopy.^{104,105} An absorption at 230 nm was assigned to the $\pi^*(2a'') \leftarrow \pi(1a'')$ transition by comparison with the results of *ab initio* calculations. In addition, two intense vacuum UV absorptions at 164.7 and 168.3 nm were reported by Fahr and Laufer¹⁰⁶.

The matrix isolation of the vinyl radical was reported by Jacox and Olson.¹⁰⁷ The radical was generated by microwave discharge of a gaseous mixture of $\text{C}_2\text{H}_2/\text{Ar}$ and trapped in argon at 12 K. For the C_s symmetrical vinyl radical, nine IR active vibrational modes are expected, seven of A' symmetry and two of A'' symmetry. An IR band near 900 cm^{-1} was assigned to the out-of-plane bending vibration mode (ν_7). Later, a prominent absorption at 900.8 cm^{-1} was assigned to this vibration on the basis of deuterium and ^{13}C -isotopic-substitution experiments.¹⁰⁸ In solid neon, this band is shifted to 895.4 cm^{-1} .⁸³ An alternative route to the vinyl radical is the thermal reaction between hydrogen atoms and acetylene under the conditions of matrix isolation (12).¹⁰⁹ Vacuum UV (120 nm) irradiation of ethylene was used to generate the vinyl radical in solid neon (Table 2).¹¹⁰

The reaction of the vinyl radical with molecular oxygen has been studied using matrix isolation IR spectroscopy.¹¹¹ The vinyl radical was produced by discharge in a $\text{C}_2\text{H}_4/\text{Ar}$ mixture and co-deposition with Ar/O_2 on top of a cold window. Annealing of these matrices produced the vinylperoxy radical $\text{C}_2\text{H}_3\text{OO}\cdot$ (13). According to calculations at the UB3LYP/6-311++G(d,p) level of theory, the reaction of $\text{C}_2\text{H}_3\cdot$ with O_2 to give $\text{C}_2\text{H}_3\text{OO}\cdot$ is exothermic by $40.8\text{ kcal mol}^{-1}$, with the s-trans conformer being 1.3 kcal mol^{-1} more stable than the cis form. Absorptions at 1140.7 and 875.5 cm^{-1} were assigned to the OO stretching and out-of-plane CH_2 bending vibrations, respectively, of the *trans*-vinylperoxy radical.

Irradiation of $\text{C}_2\text{H}_3\text{OO}\cdot$ with visible light produced a weakly bound complex between $\cdot\text{CH}_2\text{OH}$

and CO, which was characterized by its vibrations at 3604.5, 2155.8, 1188.2, 1063.9, and 494.4 cm⁻¹.¹¹¹

3.3 Propargyl Radical

The propargyl radical C₃H₃• plays a central role as a precursor of benzene in many gas phase processes, including combustion^{112–114} and atmospheric chemistry.¹¹⁵ The most important gas phase reaction of C₃H₃• is the dimerization to produce benzene (14).¹¹⁶

The bond dissociation energy DH_{298} of the methyl CH bond in propyne was determined to be 90 ± 3 kcal mol⁻¹, and the heat of formation $\Delta_f H_{298}$ of C₃H₃• was determined to be 83 ± 3 kcal mol⁻¹.^{44,117} Thus, the radical stabilization energy of the propargyl radical is similar to that of the allyl radical, indicating a similar amount of delocalization of the unpaired electron. This has been confirmed by EPR measurements¹⁰⁰ and by quantum chemical calculations.^{17,118,119} The electronic structure of the propargyl radical is represented best by the propargyl and allenyl resonance structures,

which contribute almost equally to the spin distribution.

On the basis of the spin density calculations, 35% of the spin is localized at C(3) and 65% at C(1).¹⁷ According to high-level computational studies, the bond lengths of the propargyl radical are between that of methyl acetylene and allene, in agreement with the resonance structures.¹⁷ The propargyl radical is a highly delocalized π -type radical with C_{2v} symmetry and X²B₁ electronic ground state.^{100,120}

The UV spectrum of C₃H₃• has been obtained in the gas phase by flash photolysis of C₃H₃Cl and C₃H₃Br where a broad band at 242 nm was assigned to the B²B₁ ← X²B₁, $\pi^*(b_2) \leftarrow \pi(b_2)$ transition.¹²⁰ Electronic absorptions at 351.9 and 343.0 nm assigned to the A²A'' ← X²B₁ and B²A'' ← X²B₁ transitions, respectively, were observed in neon matrix at 5 K.¹²¹ From a high-resolution rotational spectrum of the propargyl radical, the ground-state rotational constants $A_0 = 288\,055.0$ MHz, $B_0 = 9523.6775 \pm 0.0060$ MHz, and $C_0 = 9206.8805 \pm 0.0060$ MHz were obtained.¹²²

The propargyl radical has 12 normal modes that are all IR active (five of a₁, three of b₁, and four of b₂ symmetry). The first IR spectrum of C₃H₃• was obtained in matrices produced by trapping the products of the vacuum UV photolysis of allene or methylacetylene.¹²³ Four IR bands at 3308, 686, 548, and 484 cm⁻¹ were assigned to the propargyl radical initially by Jacox and Milligan,¹²³ but later the band at 548 cm⁻¹ was reassigned to triplet propargylene.¹²¹ Higher yields of C₃H₃•, which allowed to assign all 12 IR bands, were obtained by FVP of propargyl iodide (HC≡CCH₂I) or dipropargyl oxalate (HC≡CCH₂OCO)₂ with subsequent trapping of the products in inert matrices (Scheme 5).¹²⁴

High yields of the propargyl radical were also obtained by thermolysis of propargyl bromide (HC≡CCH₂Br) or butyne nitrite (HC≡CCH₂ONO) in a hyperthermal nozzle in the presence of high pressure of argon (Scheme 5). Expansion into a

Scheme 5 Synthesis of the propargyl radical.

vacuum system formed a supersonic jet, which was trapped on a cold spectroscopic window to form an argon matrix.¹⁷ The high quality of the matrices obtained by this method allowed to observe nine IR transitions. The symmetry of these transitions was determined by measuring the IR dichroism in partially oriented matrices after photolysis with polarized 248-nm light (Table 3). Zhang *et al.*¹²⁵ were able to assign the out-of-plane bending mode ν_8 at $378.0 \pm 1.9 \text{ cm}^{-1}$ and a number of overtones and combination bands (Table 3).

The propargyl radical reacts with oxygen in solid argon to produce the propargyl peroxy radical, which suggests that this reaction occurs with a very

small or no barrier (15).¹²⁶

Two isomeric products are obtained from this reaction, the propargyl peroxy and the allenyl peroxy radical (15 and 16).

On the basis of the QCISD(T,Full)/6-311++G (3df,2pd) calculations, the addition of O_2 to the CH_2 group of $\text{C}_3\text{H}_3\cdot$ is dominating at low temperatures, whereas the addition to the CH group becomes the dominant process at higher temperatures.¹¹⁶ The barrier for the O_2 addition to the CH_2 group was estimated to be $3.4 \text{ kcal mol}^{-1}$ lower than that to the CH group, which suggests that under the conditions of matrix isolation, preferentially $\text{HC}\equiv\text{CCH}_2\text{OO}\cdot$ is formed.¹¹⁶ Jochowitz *et al.*¹²⁶ calculated the bond energies of the peroxy bond at the CBS-QB3 level of theory. From the analysis of the IR spectrum of the reaction product including measuring the IR dichroism in partially oriented matrices, it was concluded that *trans*- $\text{HC}\equiv\text{CCH}_2\text{OO}\cdot$ was

observed in the matrix and not the isomeric $\text{CH}_2=\text{C}=\text{CH}-\text{OO}^\bullet$ (Table 3).¹²⁶

3.4 Allyl Radical

Ellison *et al.* carefully measured the bond dissociation energy DH_{298} of the methyl group of propene as $88.4 \pm 0.4 \text{ kcal mol}^{-1}$ and the heat of formation $\Delta_f H_{300}$ as $41.4 \pm 0.4 \text{ kcal mol}^{-1}$. This bond dissociation energy is around 12 kcal mol^{-1} lower than that of ethane ($DH_{298}(\text{CH}_3\text{CH}_2-\text{H}) = 101.1 \pm 0.4 \text{ kcal mol}^{-1}$), which results from the resonance stabilization of the unpaired electron in the allyl radical.¹¹⁷ EPR studies^{127,128} and numerous absorption measurements^{129–131} suggest that the allyl radical is planar with C_{2v} symmetry and its electronic configuration in the ground state is X^2A_2 .

The electronic absorption spectrum of the allyl radical was reported by Currie and Ramsay.¹³² Flash photolysis of several precursors produced a band at 408.3 nm that was assigned to a transition ($A^2B_1 \leftarrow X^2A_2$) of the allyl radical. This assignment was later confirmed by cavity ring-down spectroscopy,¹³³ picosecond time-resolved photoelectron spectroscopy,¹³⁴ and photofragment action spectroscopy.¹³⁰ A UV absorption near 224 nm was assigned to a transition into an upper state of 2B_1 symmetry.¹³⁵ Maier *et al.* measured the UV–vis absorption spectrum of the allyl radical in an argon matrix and reported a strong band at 213 nm and a weak band centered at 408.5 nm.¹³⁶ Resonant multiphoton ionization allowed to detect three transitions in the region between 238 and 250 nm, which were assigned by using their symmetry and isotopic shifts.¹³¹ More recently, the vibronic spectra of the 3s and 3p Rydberg states of the jet-cooled allyl radical was identified by resonance-enhanced multiphoton ionization combined with electronic ground-state depletion spectroscopy.¹³⁷

The allyl radical has 18 normal modes (seven of a_1 , two of a_2 , three of b_1 , and six of b_2 symmetry), of which the two a_2 modes are not IR active. Slit discharge supersonic expansion has been used to obtain the high-resolution IR spectra of the jet-cooled allyl radical at low

temperature ($T_{\text{rot}} \approx 20 \text{ K}$) in the CH_2 stretching region.¹³⁸ The in-phase (ν_1) and out-of-phase (ν_{13}) asymmetric CH stretching vibrations were observed at 3113.98 and 3110.60 cm^{-1} , respectively. In the region between 3045 and 3010 cm^{-1} , bands at 3033.87, 3023.46, and 3020.32 cm^{-1} were assigned to the CH stretching vibrations ν_2 , ν_3 , and ν_{14} , respectively.¹³⁹

The first matrix IR spectrum of the allyl radical was reported by Maltsev *et al.*¹⁴⁰ who reported 16 vibrational modes of the allyl radical in argon. Later Maier¹³⁶ and Oth¹⁴¹ were also investigating the allyl radical; however, several assignments of vibrational modes were not consistent with each other. This was solved by measuring the deuterated isotopomers $\text{CH}_2\text{CHCH}_2^\bullet$, $\text{CH}_2\text{CDCH}_2^\bullet$, and $\text{CD}_2\text{CDCD}_2^\bullet$ and the IR dichroism of the IR transitions in partially oriented matrices.¹⁸ UV irradiation at 351 nm with polarized light leads to a partial bleaching of the IR bands of the allyl radical and formation of a new product. By comparison with DFT calculations, all observed vibrations could be assigned according to their symmetry (Table 4).¹⁸

Upon irradiation with 410-nm light (argon matrix), the allyl radical rearranges to the cyclopropyl radical (Scheme 6), which in addition allowed to record the IR spectrum of the cyclopropyl radical. Of the 18 IR active normal modes of the cyclopropyl radical, 16 were observed and assigned.¹⁴¹ From these IR data, it was concluded that the cyclopropyl radical is a σ radical with C_s symmetry (Table 4).

4 ARYL RADICALS

4.1 Phenyl Radical

The phenyl radical ($\text{C}_6\text{H}_5^\bullet$) is the archetypical aromatic σ radical of very high reactivity. It plays a key role in many gas phase and high temperature processes such as combustion and soot formation,¹⁴² formation of polycyclic aromatic hydrocarbons (PAHs),¹⁴³ and the chemistry of the interstellar gas and circumstellar envelopes.¹⁴⁴ It also plays a role as reactive intermediate in many organic reactions.^{145,146} Because of its fundamental importance, the phenyl radical has been extensively studied both experimentally and theoretically. Formally, the phenyl radical is derived from benzene

by homolytic cleavage of one of the CH bonds with a bond dissociation energy DH_{298} of 112.9 ± 0.5 kcal mol⁻¹. From that for the phenyl radical, the heat of formation $\Delta_f H_{298}$ of 80.5 ± 0.5 kcal mol⁻¹ was determined.¹⁴⁷

The EPR spectrum of C₆H₅^{*} reported by Bennett *et al.* revealed a C_{2v} structure and an ²A₁ electronic ground state.^{148,149} Later, Kasai *et al.* confirmed that the unpaired electron is localized mainly in a σ -type orbital.¹⁵⁰ In these experiments, C₆H₅^{*} was generated by the photolysis of phenyl iodide in an argon matrix at 4 K. The EPR spectrum of the phenyl radical shows the expected hyperfine coupling of the unpaired electron with two *ortho* ($a_{xx} = 2.19$ mT, $a_{yy} = 1.54$ mT, $a_{zz} = 1.49$ mT), two *meta* ($a_{xx} = 0.66$ mT, $a_{yy} = 0.61$ mT, $a_{zz} = 0.50$ mT), and one *para* ($a_{xx} = 0.20$ mT, $a_{yy} = 0.25$ mT, $a_{zz} = 0.12$ mT) hydrogen atom.

The electronic absorption spectrum of matrix-isolated C₆H₅^{*} in the region of 52 000–4000 cm⁻¹ consists of three band systems corresponding to the A²B₁ ← X²A₁ transition at 510.5 nm, the B²A₁ ← X²A₁ transition at 235.1 nm, and the C²B₂ ← X²A₁ transition at 211.5 nm.¹⁵¹ The symmetry of the electronic transitions was obtained from polarization measurements on photooriented samples.¹⁵¹

The rotational spectrum of C₆H₅^{*} produced by discharge in benzene/argon mixtures was obtained in a supersonic molecular beam.¹⁵² Fourteen rotational transitions between 9 and 40 GHz and over 50 transitions between 150 and 330 GHz were measured for the normal isotopic species. The rotational constants were assigned with the help of CCSD(T)/cc-pVTZ calculations. The high-resolution IR spectrum of the jet-cooled phenyl radical was obtained in a supersonic expansion.¹⁵³

The phenyl radical can be generated by photolysis or pyrolysis of a variety of precursors such as benzoic anhydride, benzoyl peroxide, iodobenzene, or nitrobenzene (Scheme 7). Pacansky *et al.*

Scheme 7 Synthesis of the phenyl radical.

reported the IR spectrum of $C_6H_5^\bullet$ produced by the photolysis of acetyl benzoyl peroxide in an argon matrix^{154,155} Ellison and coworkers were able to record all 24 IR active transitions of $C_6H_5^\bullet$ in matrices produced by matrix photolysis of benzoyl peroxide or benzoyl anhydride.^{156,157} In addition, the symmetry and absolute intensities of the IR modes were reported (Table 5). The Raman active modes were assigned with the help of the isotopic shifts after ^{13}C substitution.¹⁵⁸

Bimolecular reactions of $C_6H_5^\bullet$ with a number of small molecules under the conditions of matrix isolation have been investigated by spectroscopy. Both in the gas phase and in an argon matrix (in the matrix annealing at 30 K is necessary to allow diffusion), the phenyl radical reacts with molecular oxygen to form the phenyl peroxy radical (17).¹⁵⁹

The reaction was calculated to be exothermic by $46.3 \text{ kcal mol}^{-1}$ at the G2M level of theory.¹⁶⁰ In that study, azobenzene was used as a new thermal precursor for the generation of $C_6H_5^\bullet$. The IR spectrum of $C_6H_5OO^\bullet$ exhibits strong bands at 1122.9 , 793.9 , and 607.2 cm^{-1} which are redshifted by 67.2 , 15.6 , and 11.8 cm^{-1} if $^{18}O_2$ is used. These bands were assigned to the $\nu(OO)$, $\nu(CO)$, and $\delta(CCO)$ vibrational modes, respectively, with the aid of DFT calculations (UB3LYP/cc-pVTZ).¹⁵⁹

Matrix-isolated $C_6H_5OO^\bullet$ exhibits a broad visible absorption at 480 nm , in agreement with cavity ring-down experiments.¹⁶¹ Irradiation ($\lambda > 400 \text{ nm}$) of $C_6H_5OO^\bullet$ results in the formation of the 2-oxepinoxy radical with the CO carbonyl stretching vibration at 1726.9 cm^{-1} . This band shows the expected large ^{18}O isotopic redshift (-30.7 cm^{-1}). Prolonged irradiation with visible light ($\lambda > 400 \text{ nm}$)

finally leads to the cleavage of the phenyl ring and formation of a mixture of conformers of a ketoketene (Scheme 8).¹⁵⁹

The thermal reaction of $C_6H_5^\bullet$ with CO in argon matrices produces the benzoyl radical with a strong CO carbonyl stretching vibration at 1824.4 cm^{-1} (18).¹⁶² The IR spectrum is in good agreement with

Scheme 8 Reaction of the phenyl radical with molecular oxygen.

DFT calculations (UB3LYP/cc-pVTZ).

This reaction was predicted by B3LYP/6-311G(d,p) calculations to be exothermic by $24.58 \text{ kcal mol}^{-1}$ with an activation barrier of only $0.7 \text{ kcal mol}^{-1}$.^{163,164} From EPR studies at 77 K, it was concluded that the benzoyl radical is a σ -type radical with an sp^2 hybridized radical center.^{165,166} The formation of the benzoyl radical is photochemically reversible. Irradiation of $\text{C}_6\text{H}_5\text{CO}^\bullet$ with UV light ($\lambda > 260 \text{ nm}$) results in the cleavage back to $\text{C}_6\text{H}_5^\bullet$ and CO. In matrices doped with both CO and O_2 , the benzoyl radical reacts further with molecular oxygen to produce the benzoyl peroxy radical (Scheme 9).¹⁶² It is remarkable that in these experiments, the phenyl radical was trapped with CO and O_2 in two subsequent steps, which could be directly monitored by IR spectroscopy. The benzoyl peroxy radical was characterized by IR spectroscopy in combination with DFT calculations.

Another interesting reaction of the phenyl radical is the reaction with water. In argon matrices doped with water, the phenyl radical forms a weakly bound complex via an $\text{OH} \cdots \pi$ interaction. This complex

Figure 6 Phenyl radical $\cdots$ water complexes calculated at the UM05-2x/6-311++G(2d,2p) level of theory.^{167,168}

was characterized by IR spectroscopy.^{167,168} In the complex, the most intense bands of $\text{C}_6\text{H}_5^\bullet$ at 705.8 and 657.4 cm^{-1} (CH out-of-plane deformation vibrations) are blueshifted by 5.6 and 2.4 cm^{-1} and the OH stretching vibration of water at 3639.7 cm^{-1} is redshifted by 21.7 cm^{-1} . This suggests that the water molecule is forming a weak $\text{OH} \cdots \pi$ hydrogen bond with the phenyl ring (Figure 6). A comparison of these IR data with calculations at the UM05/6-311++G(2d,2p) level of theory suggests that indeed the energetically most stable complex A is formed. C and D are very weak van der Waals complexes, whereas B is a pre-reactive complex

Scheme 9 Reaction of the phenyl radical with carbon monoxide and oxygen.

with an $\text{OH}\cdots\text{C}$ interaction pointing toward the radical center.

Surprisingly, visible light ($\lambda > 420\text{ nm}$) irradiation results in hydrogen atom transfer from water to the phenyl radical and formation of a second, highly labile complex between benzene and the OH radical with distinct absorptions at 3502.2, 1482.8, 1040.3, and 684.2 cm^{-1} . If H_2^{18}O is used, the OH stretching vibration of the benzene $\cdots\text{HO}^\bullet$ complex shows an isotope shift of -11 cm^{-1} , which proves that indeed a complex of the $\text{HO}^\bullet$ radical is observed. Obviously, there is a small activation barrier that prevents the $\text{HO}^\bullet$ radical from reacting with benzene. This activation barrier can be overcome by prolonged photolysis with $\lambda > 420\text{ nm}$ light, resulting in the complete destruction of the aromatic ring of the benzene $\cdots\text{HO}^\bullet$ complex and formation of a highly unsaturated ketene (Scheme 10). The mechanism of this reaction was investigated in detail by calculations at the UB3LYP/6-311++G(2d,2p) level of theory.

Derivatives of the cyclohexadienyl radical are important intermediates in radical reactions involving aromatic systems. The parent radical $\text{C}_6\text{H}_7^\bullet$ was generated in a xenon matrix by the reaction of benzene with hydrogen atoms at 45 K and characterized by EPR and IR spectroscopy (19).¹⁶⁹

In the IR spectrum, a very strong doublet at 618 and 620 cm^{-1} and several other weak absorptions were assigned to the cyclohexadienyl radical based on DFT calculations. The EPR spectrum shows a triplet of quartets owing to the large hyperfine

coupling with the two CH_2 protons and a weaker coupling with the three equivalent CH protons.¹⁶⁹

4.2 Benzyl Radical

The benzyl radical, $\text{C}_7\text{H}_7^\bullet$, is another fundamental species that plays a role in combustion processes^{170,171} and in the chemistry of the atmosphere.¹⁷² The bond dissociation energy DH_{298} of a CH bond in the methyl group in toluene was determined to be $89.8 \pm 0.6\text{ kcal mol}^{-1}$ and the heat of formation of the benzyl radical to be $49.7 \pm 0.6\text{ kcal mol}^{-1}$.¹¹⁷ This CH bond dissociation energy is about 12 kcal mol^{-1} lower than that of a saturated system, which indicates the large resonance stabilization of the benzyl radical.^{173,174} Extensive experimental^{175–177} and theoretical studies^{178,179} conclude that the benzyl radical is an aromatic π -type radical with a C_{2v} symmetry and a $^2\text{B}_2$ electronic ground state.

EPR spectra of the benzyl radical could be obtained after FVP of phenacyl iodide followed by matrix isolation of the products with a large excess of argon or neon.¹⁸⁰ The isotropic coupling constants of the matrix-isolated benzyl radical are close to those measured in solution ($A(\text{H}_\alpha) = 16.40$, $A(\text{H}_o) = 5.17$, $A(\text{H}_m) = 1.77$, and $A(\text{H}_p) = 6.19\text{ G}$, respectively).

Scheme 10 Reaction of the phenyl radical with water.

LIF and multiphoton ionization spectroscopy were used to gain insight into the electronic structure of the benzyl radical.¹⁷⁷ The UV spectrum of the benzyl radical, matrix-isolated in neon, exhibits an absorption at 454.4 nm assigned to the $1^2A_2 \leftarrow 1^2B_2$ transition. Another band at 305.5 nm was attributed to the $2^2A_2 \leftarrow 1^2B_2$ transition, and a broad band at 245 nm corresponds to the $3^2B_2 \leftarrow 1^2B_2$ transition.¹⁸¹ The emission spectrum of the benzyl radical was obtained by UV photolysis of toluene and toluene- d_8 in an argon matrix.¹⁷⁵ The emission band at 457.4 nm is in good agreement with that observed in the gas phase at 454.5 nm.¹⁸²

FVP of benzyl bromide ($C_6H_5CH_2Br$) or 1,2-diphenylethane ($C_6H_5CH_2$)₂ with subsequent trapping in argon produced high yields of the matrix-isolated benzyl radical ($C_6H_5CH_2\cdot$) that could be characterized by IR spectroscopy. The CH stretching vibration $\nu_{as}(CH_2)$ at 3111 cm^{-1} is in accordance with the sp^2 hybridization of the methylene carbon atom, as predicted by theory. This is in line with the frequency of the C–CH₂ stretching vibration found at 1264 cm^{-1} , which is considerably higher than the C–CH₃ stretching vibration of toluene at 1215 cm^{-1} , indicating the sp^2 hybridization of the methylene carbon atom and strong resonance stabilization of the radical.^{22,183}

4.3 Phenoxyl Radical

The phenoxyl radical, $C_6H_5O\cdot$, is another aromatic radical of fundamental importance in many reactions, such as combustion of organic compounds.¹⁸⁴ Derivatives of the phenoxyl radical, such as the tyrosyl radical, are important biological intermediates,¹⁸⁵ which has triggered a large number of experimental and theoretical studies on these systems.^{186,187}

The phenoxyl radical is formally obtained by homolytic cleavage of the OH bond of phenol. The bond dissociation enthalpy DH_{298} of this bond was determined to be $90 \pm 3\text{ kcal mol}^{-1}$, and subsequently the heat of formation $\Delta_f H_{298}$ of phenoxyl to be $-58 \pm 3\text{ kcal mol}^{-1}$.¹⁸⁸ The phenoxyl radical is a π radical that is stabilized by delocalization of the unpaired electron into the π system of phenyl ring. This results in a partial double bond character of the CO bond, which

is in accordance with EPR^{189–193} and theoretical studies.^{186,187}

The phenoxyl radical shows C_{2v} symmetry and a $2B_1$ electronic ground state. There has been some debate in literature concerning the CO bond length, which varies depending on the level of calculations used, between 1.22 and 1.38 Å. High-level *ab initio* calculations (CAS-SCF/6-311G(2d,2p)) predict a CO distance of 1.228 Å, in the range of typical CO double bonds, and CC bond distances similar to that expected for a quinoid structure.¹⁹⁴ This stresses the importance of quinoid resonance structures for the description of the electronic structure of the phenoxyl radical.

The resonance Raman spectra of phenoxyl, phenoxyl- d_5 , and phenoxyl-2,4,6- d_3 were obtained in water after photoexcitation of phenol at 400 nm.^{195–197} The strongest band at 1505 cm^{-1} was assigned to the CO stretching mode.¹⁹⁸ In phenoxyl- d_5 , and phenoxyl-2,4,6- d_3 , this band is shifted to 1489 and 1487 cm^{-1} , respectively. The band at 1505 cm^{-1} observed in a UV resonance Raman study was shifted by 13 cm^{-1} on ^{17}O substitution, indicating a large contribution of the CO stretching mode.¹⁹⁹ The low frequency of this mode (compared to “normal” CO double bonds) reflects the only partial double bond character in phenoxyl.

The first electronic spectrum of the phenoxyl radical was reported by Porter and coworkers.²⁰⁰ There was some debate concerning the assignment of the symmetry of the ground state.²⁰¹ Vacuum UV photolysis of matrix-isolated phenol or anisole produced phenoxyl with several UV absorptions between 397.2 and 367.5 nm.²⁰² In a comprehensive study, the phenoxyl radical was obtained in solid argon by laser photolysis of phenol, diphenyl carbonate, nitrosobenzene, or nitrobenzene (Scheme 11).²⁰¹ In the UV–vis region, the spectrum exhibits four electronic transitions with origins at 626, 398, 295, and 239 nm, assigned to transitions to $2A_2$, $2B_1$, $2A_2$, and $2B_1$ states, respectively, by measuring the linear dichroism in partially photooriented matrices.²⁰¹

Scheme 11 Reaction channels for the synthesis of the phenoxy radical.

The phenoxy radical shows 30 normal vibrational modes, of which 27 are IR active. In an extensive study, 26 vibrational modes of $C_6H_5O^\bullet$ were measured in an argon matrix and assigned by isotopic labeling ($C_6D_5O^\bullet$ and $^{13}C^{12}C_5H_5O^\bullet$ were investigated) and measuring the IR dichroism in photoselection experiments.²⁰³

An intense band at 1481 cm^{-1} was assigned to the CO stretching vibration (ν_7), which differs slightly from the band at 1505 cm^{-1} observed by Raman spectroscopy in aqueous solution.^{196,199} The discrepancy results from specific interactions (hydrogen bonding) between the CO group and water. The shifts observed after isotopic labeling is in agreement with the results from the Raman experiments and confirms the assignment of the CO stretching vibration (Table 6).²⁰³ The complete set of experimental frequencies of $C_6H_5O^\bullet$ observed in argon matrix is listed in Table 6.

An interesting derivative of phenoxy that was also investigated in argon matrices is the 2-hydroxyphenoxy radical.²⁰⁴ UV photolysis ($\lambda > 220\text{ nm}$) of 2-nitrophenol results in the rearrangement to 2-hydroxyphenyl nitrite into its *s-trans* conformation. Prolonged irradiation produces 2-hydroxyphenoxy radical and NO, which on annealing of the matrices react thermally to a mixture of *s-trans* and *s-cis* 2-hydroxyphenyl nitrite. The 2-hydroxyphenoxy radical has a strong absorption at 3336 cm^{-1} , which is assigned to the OH stretching mode. The redshift compared to the OH stretching mode in phenol (3638.5 cm^{-1})²⁰⁵

Table 6 Vibrational frequencies of the phenoxy radical.

Scheme 12 Photochemistry of 2-nitrophenol.

reveals a strong intramolecular OH $\cdots$ O hydrogen bond (Scheme 12). This assignment was supported by DFT calculations (B3LYP/6-31++G(d,p)).

5 CONCLUSION

The isolation and spectroscopic characterization of highly reactive free radicals was one of the driving forces for the development of the matrix isolation technique five decades ago. Since that time, the field has become mature and the development of easy to use, powerful cryostats, highly sensitive spectrometers (in particular FTIR), and advanced computational methods that allow to simulate the spectra of elusive species made matrix isolation the method of choice for the investigation of free radicals. In particular, the simulation of spectra by using DFT methods has dramatically reduced the risk of incorrect assignments of spectra, which was common in the early days of matrix isolation. One has to keep in mind that many species isolated in matrices are unprecedented with no reference compounds to compare with. IR and EPR spectroscopy proved to be the most important spectroscopic methods for the characterization of radicals, and in combination with quantum chemical calculations, detailed insights into the geometry, electronic structure, and many other properties of radicals are now available. The most severe limitation for the matrix isolation of radicals is the availability of suitable precursors. A more recently developing application of the matrix isolation technique is the investigation of bimolecular reactions by carefully controlling the diffusion of trapped species. In particular, reactions with molecular oxygen, CO, CO₂, and other small molecules have been studied. This leads to highly labile peroxy radicals, acyl radicals, and other species that previously could not be isolated. These studies are important since they link matrix isolation to the more traditional solution and gas phase chemistry.

1 INTRODUCTION

In solution, radicals are viewed as reactive intermediates that have a significant impact on the outcome of chemical reactions, but are usually short-lived. A thorough analysis shows on the other hand that many radicals are only kinetically unstable, that is, the barriers to chemical reactions are low and collisions almost always lead to a reaction. The most important reaction for the depletion of radicals often is their recombination. Once this process is sufficiently hindered, the fate of free radicals can even be followed in the bulk, as, for example, the time-honored triphenylmethyl radicals discovered by Gomberg (see **The History of Free Radical Chemistry**).¹ Thermochemically, however, many radicals are quite stable.² Under isolated conditions such radicals are then long-lived and can be studied in detail. This permits to gain insight into the structure and dynamics that is not available from solution-phase experiments. There are two major reasons to study chemical reactions of isolated radicals. First, owing to their open-shell electronic structure and high reactivity, radicals are employed as model compounds for chemical reaction dynamics. In this respect, the existence of low-lying electronically excited states renders radicals a particular challenge for theoretical chemistry. Therefore, detailed studies which allow for a direct comparison of

experimental data with *ab initio* computations serve as important benchmarks for the evaluation of contemporary theoretical methods. This in turn can help to improve the insight into the chemistry occurring in solution. Second, isolated radicals are in fact of considerable chemical importance. Specifically, they are key species in the chemistry of numerous environments and processes, such as

1. Combustion processes.^{3–6}
2. Atmospheric chemistry.⁷
3. Low-temperature plasmas.^{8,9}
4. Interstellar chemistry.¹⁰
5. Biochemical processes¹¹ including prebiotic chemistry.¹² Owing to the importance of the subject, the whole Volume 3 of this encyclopedia is dedicated to radicals in biochemical processes.

A large part of the basic research on free radicals is driven by the desire to understand the chemistry of these systems. Thermochemical data, structural information, rate constants, and information on the reaction dynamics are required and can be obtained from investigations of radicals in the gas phase. In this contribution, we summarize the contemporary means to achieve specific and detailed information about the intrinsic properties and the elementary reactions of free radicals in the gas phase.

Owing to the richness of information available in the whole field of isolated radicals in the gas phase, we focus on certain aspects, while omitting others. Specifically, the following criteria were applied to limit the topics discussed in detail. (i) Stable species that are formally radicals or biradicals, but can be filled in bottles, are excluded, examples being $\text{NO}^\bullet$, $\text{NO}_2^\bullet$, or the triplet ground state of O_2 . (ii) Despite being worth considerable interest on their own, we do not include the reactions of single atoms, even if these are open-shell species, reactive, and of considerable chemical importance (e.g., in the radical halogenation of alkanes). (iii) Since the focus of this article is on *reactions* of isolated radicals, to a large extent we ignore the extensive work on the *spectroscopy* of isolated radicals, unless it is relevant for the discussion of chemical reactions. We refer the reader, for example, to the articles **Analysis of Radicals by EPR** and **Matrix Isolation of Radicals**. Owing to the research interest of the authors, the focus is mostly on organic radicals, but the concepts and experimental strategies applied as well as the general conclusions derived also apply for radicals of other main-group elements. On the other hand the term “radical” loses most of its conceptual meaning in the chemistry of transition metals, lanthanides and actinides. In lanthanide compounds, for example, the unpaired electrons in the f-shell can almost be regarded as “core-like” electrons and do often not participate in the chemistry, while the compounds as such have, of course, open-shell character.¹³

2 CHEMICAL SYSTEMS DOMINATED BY RADICALS

Above we have summarized the environments in which radicals are crucial for the chemistry taking place. In the next subsections, we outline their role in more detail.

2.1 Combustion Research

Combustion ranging from smoldering via engines to open fire is the culturally, technologically, and economically most important process dominated by radicals. The urge to understand the elementary chemical processes in combustion engines is a

major driving force for a large part of free radical research. A particular challenge in this respect is the introduction of biofuels, which are chemically much more complex than the conventional fuels on the basis of crude oil. The foundations of combustion research are described in textbooks¹⁴ and only some selected key aspects are summarized here. Many reactions occur in a flame or a combustion engine, among them the cleavage of C–C bonds at high temperature, which leads to two radicals, one of them often a methyl radical (reaction 1).

Central in combustion is the interaction of initially formed hydrocarbon radicals $\text{R}^\bullet$ with molecular oxygen (reactions 2–4), which *inter alia* lead to oxy- and peroxyradicals that undergo further reactions.

Particularly important with regard to combustion is the generation of two new radicals in the cleavage of the hydroperoxide in reaction (4), which leads to the exponential increase of the rate of combustion, once radical processes are initiated sufficiently fast. Other important reactions shown are the dimerization of radicals (reaction 5), hydrogen abstractions, and hydrogen additions (reactions 6 and 7) as well as the fragmentation of radicals into others (reaction 7). The latter two processes can be bimolecular or unimolecular in nature.

These few examples illustrate the wide range of radical reactions that are important in combustion. Whether a certain reaction occurs and to what extent it is important, depends on numerous factors, such as the composition of the fuel, the temperature, and the pressure. In modern technology, the optimization of combustion engines is therefore accompanied by an explicit kinetic modeling of the combustion reactions.^{15,16} Such kinetic models contain

Scheme 1 The dimerization of two propargyl radicals yields an aromatic unit in a single bimolecular step followed by several unimolecular isomerizations.

a large manifold of species that are interconnected by numerous chemical reactions. A large number of rate constants and thermochemical data are therefore required for a satisfactory description. However, accurate rate constants are difficult to obtain experimentally, in particular, for the reactions of radicals. Notwithstanding these difficulties, radicals frequently serve as the key species in the respective kinetic schemes. They often constitute branching points in chain reactions and in many cases there exist several reaction channels with comparable energetics. Alkyl radicals, for example, can lose a hydrogen atom in a unimolecular dissociation or they can abstract a H-atom from another molecule (or radical) in a bimolecular reaction, for example, reactions (6) and (7). The relative importance of the two pathways depends on various parameters, such as the pressure, the temperature, and the concentration of the various species.

Ideally, *in situ* monitoring of the reactions occurring in engines is carried out by following the concentration of characteristic species using laser spectroscopic methods, in particular laser-induced fluorescence (LIF) or coherent anti-Stokes Raman spectroscopy.¹⁷ In most cases, NO[•] and OH[•] are monitored, because of their high concentrations and cross-sections. The methods are quite sophisticated and have been described in several reviews and textbooks.⁶ Monitoring hydrocarbon radicals *in situ* would be helpful, but concentrations are generally too small. In this respect, recent photoionization experiments with tunable synchrotron radiation (SR) are quite promising for the rapid on-line monitoring of open-shell species formed in combustion.⁴ One of the most important challenges in combustion research is to understand the formation of polycyclic aromatic hydrocarbons (PAHs) and soot, because of both the carcinogenic potential and the engine damage associated with them. Experiments in flames suggest that formation of the first aromatic units is central.³ Subsequent reactions building up larger aromatic structures are then comparably fast. Hydrocarbon radicals are known to be important intermediates in the early stages of

soot formation, even though they only appear in small concentrations.^{3,18–21} Radicals with C₃ units are particularly relevant,²² because an aromatic C₆ unit can be formed in one bimolecular reaction step only,²³ as shown for the dimerization of two propargyl radicals in Scheme 1. All further reactions after the initial dimerization are unimolecular in nature.

Other important reaction pathways to the first aromatic ring include acetylene and C₄ or C₅ units^{3,23} as shown in Scheme 2. The accuracy of kinetic models describing combustion systems and in particular the formation of PAH and soot depends on the rates of many different elementary reactions, forming a considerable task for laboratory chemists interested in gas-phase radical reactions. The large amount of compounds formed in a combustion process and of possible reaction pathways makes this a formidable challenge.

In recent years, the so-called “alternative” or “biofuels,” derived from agricultural products (such as palm oil, corn, sugarcane, and soy beans) or even from agricultural waste, have received growing interest. In addition to few pure hydrocarbons, biomass includes many oxygen- or nitrogen-containing species. Upon combustion of these novel fuels, a number of radical species will appear that are not present with conventional fuels and have thus only poorly or even not at all been characterized.⁴ Modeling the combustion of biofuels requires additional data on such radicals. This serves as a strong motivation for scientists to investigate the largely unexplored chemistry of N-containing radicals in more detail.

Scheme 2 Important C–C coupling reactions of C_n-radicals (*n* = 3–5).

Hydrocarbon cracking is related to combustion. Long-chain hydrocarbons are broken down to saturated or unsaturated species containing less carbon atoms. This requires the breaking of carbon–carbon bonds and leads to hydrocarbon radicals, in particular alkyl radicals. Many reactions are similar to those that appear in combustion chemistry. Modeling cracking, such as modeling combustion, thus requires considerable knowledge about the kinetics of radical reactions.²⁴

2.2 Atmospheric Chemistry

Radicals are ubiquitous in the earth's atmosphere. In particular, oxygen-containing radicals, such as OH[•] and OOH[•], dominate its chemistry; note that O₂ itself also is an open-shell species. Owing to the importance of radical chemistry in the earth's atmosphere, a whole article of this handbook is devoted to the subject of "Atmospheric Radical Chemistry" (see **Atmospheric Radical Chemistry**). Thus, we will not discuss the chemistry of the earth's atmosphere in any further detail. However, other planets and their moons also bear atmospheres. Their chemistry came into focus recently because of the NASA/ESA Cassini–Huygens mission, which aimed at exploring the planets Jupiter and Saturn as well as their moons. In particular Titan,

a moon of Saturn, is of interest here.^{25,26} The main constituents of its atmosphere are nitrogen, methane, and argon. In Figure 1 the Titan atmosphere is compared with that of earth. While earth has an oxidizing atmosphere (containing O₂ instead of CH₄) dominated by oxygen-containing radicals, Titan has a reducing atmosphere dominated by hydrocarbon radicals (including nitrogen-containing species). A surprisingly large number of radicals and ions has been observed in the fly-by of Huygens.^{27,28} A large part of the interest in the Titan atmosphere stems from the fact that this particular atmosphere is believed to resemble that of the early earth. Studying its chemistry might thus provide hints on how complex organic and bioorganic molecules were formed on the earth, a field termed "astrobiology" or "exobiology."²⁹

2.3 Plasma Chemistry

A plasma can be described as a collection of (charged and neutral) particles that appears neutral but is a conductor of electrical current. In the so-called low-temperature plasmas, chemistry is initiated by hot electrons (temperatures on the order of some 10⁴ K), whereas ions and molecules can be comparably cold, that is, around room temperature. Low-T plasmas are of considerable technical importance and are used for surface modification and functionalization,^{30,31} for lighting (an example being the so-called energy saving lamp), displays (plasma TV), or the cleaning of archeological artifacts.^{32,33} The electron–molecule interactions generate ions and radicals that dominate an often complex and poorly understood chemistry. Numerous reactive species have been identified in plasmas and are monitored in plasma diagnostics,⁹ among them CF_n or SiX_n (X = Cl, F) that occur in CF₄, SF₆, or Cl₂ plasmas used for etching of Si and SiO₂ surfaces. The chemistry of reactive species determines to a large extent the selectivity and the rate of the etching process. For example, fluorocarbon plasmas are reported to selectively etch Si over SiO₂.⁹ Some of the relevant questions in plasma chemistry are, therefore, (i) which species are deposited on surfaces, (ii) which species lead to surface etching, and (iii) what effect do transient species have on the chemistry going on at the surface? To answer these questions, a profound

Figure 1 Comparison between the atmospheres of earth and Titan, taken from 26. [Reprinted by permission from Macmillan Publishers Ltd: Nature, 438, 756–757, Copyright 2005.]

Figure 2 Important chemical reactions in a CH_4/H_2 plasma, taken from Ref. 35. [Reproduced with permission from J. Röpcke, L. Mechold, X. Duten, A. Rousseau, A time resolved laser study of hydrocarbon chemistry in H_2 - CH_4 surface wave plasmas, *J. Phys. D: Appl. Phys.*, **34**, 15, 2336–2345, 7th August 2011, IOP Publishing. DOI: 10.1088/0022-3727/34/15/313.]

knowledge on the chemistry of ions, radicals, and carbenes is required. For the modeling of hydrocarbon plasmas that are used for the deposition of diamond films on surfaces, a large number of radical reactions has to be included.³⁴ Figure 2 shows the species detected in a CH_4/H_2 discharge and the reactions that connect them.³⁵ As visible in the figure, several small hydrocarbon radicals and carbenes are in the center of this reaction network. The relative rates of the various reactions determine the concentrations of intermediates and products. Modeling plasma processes³⁶ requires accurate kinetic data on the reaction of isolated radicals, similar to the modeling of a combustion engine. However, the inclusion of surface reactions provides an additional challenge.

2.4 Interstellar Chemistry

Interstellar space is a hostile environment for chemistry, because high-energy radiation is abundant. Thus even chemists are sometimes surprised to hear that radicals play a crucial role in the formation of complex molecules in interstellar space. As mentioned in the introduction, radicals are kinetically unstable, but can be thermochemically stable. In a low-temperature environment with low collision rates, radicals and ions can therefore exhibit long lifetimes. Regions of space consisting of neutral matter, termed *molecular clouds*³⁷ can be formed in-between stars and within planetary systems. Atomic and molecular densities range

from 10^2 cm^{-3} (diffuse clouds) to 10^6 cm^{-3} (dense clouds). A density of 10^4 cm^{-3} corresponds to a pressure on the order of 10^{-14} mbar. Since such low pressures are hard to achieve in a laboratory, the name “dense” sounds somewhat euphemistic. A back-of-the envelope estimate for H_2 (the by far most abundant species in molecular clouds), using simple gas kinetics shows that hydrogen at a temperature of 10 K experiences a mean free path of more than 10^9 m (assuming a collision cross section of roughly 10^{-18} m^2 , note that cross sections are strongly energy dependent) and a time between collisions on the order of 10^7 seconds, which corresponds to roughly three months. This estimate for hydrogen shows that reactions between molecules will be rare; note, however, that time is not a real limitation in astronomical context. Moreover, the average temperatures in interstellar clouds are on the order of only a few Kelvin, such that only reactions with low barriers and high cross sections will significantly contribute to the chemistry. So one might wonder how complex molecules can be formed in molecular clouds that are thought to be the cradle of star formation. Notwithstanding these obstacles, several types of reactions can occur in interstellar environments. One class are ion–molecule reactions because the long-range attractive potential of ions increases the collision cross-section with neutral molecules and because ion–molecule reactions often occur without a barrier. Furthermore, some reactions are supposed to proceed on the surface of small grains.³⁸ Nevertheless both pathways cannot explain all of the chemistry observed. In recent years, it was proposed that radical–radical and radical–molecule reactions do also contribute to the formation of complex molecules. Despite the rather low number densities of open-shell species in the interstellar space, they can in fact play a significant role for the growth of larger molecules because the activation barriers associated with the reactions of radicals often are low, such that the reactive events can occur close to collision rate.³⁹ Among the unsaturated species observed in space^{40–42} are molecules as exotic as polyynes of the type $\text{C}_m\text{H}^\bullet$ with $m \leq 8$ and $\text{HC}_m\text{CN}^\bullet$ with m ranging up to 10. Another important species is cyclopropenylidene, $c\text{-C}_3\text{H}_2$, a carbene with a free electron pair. Their number densities relative to H_2 are on the order of 10^{-8} . Despite the small concentrations, the formation of complex molecules in the universe cannot be explained without taking reactions of radicals and carbenes into

account. However, for modeling purposes the rate constants for such reactions have to be known accurately at temperatures as low as 10 K, which poses a considerable challenge to the laboratory scientists. A method that overcomes this obstacle, Cinétique de Réaction en Ecoulement Supersonique Uniforme, abbreviated as CRESU, is introduced in Section 6.

3 EXPERIMENTAL CONSIDERATIONS

3.1 How to Study Isolated Radicals

Due their kinetic instability, the structure, thermochemistry, and unimolecular reactions of radicals are preferentially studied under collision-free conditions. A suitable approach is free jet spectroscopy.^{43–45} In this technique, the molecule of interest is diluted in 1–2 bar of a rare gas (typically He or Ar) and this mixture is expanded through a small nozzle (diameter 0.1–1 mm) into the vacuum. Pulsed operation allows to maintain a low pressure and matches the duty cycles of the typical laser systems. In the subsequent adiabatic expansion, energy is transferred to translational energy of the rare gas and the molecules cool vibrationally and rotationally. After a couple of centimeters the process is completed and a cold beam is formed, in which the molecules travel with almost equal speed into the same direction and no further collisions occur. Such beams are not limited to applications in spectroscopy but permit to study the structure, dynamics, and thermochemistry of reactive species in general. While stable molecules can be cooled to a few K, radical beams are in general warmer, as discussed in the next section.

3.2 The Generation of Isolated Radicals

It is still a challenge to generate radicals cleanly and in a number density sufficient to perform gas-phase experiments. In addition, it is often unavoidable to generate, beside the species of interest, a second fragment from the precursor that can in principle interfere in the experiment. Typically a chemical bond in a suitable precursor is cleaved by means of pyrolysis, photolysis, electric discharges, or a chemical reaction. Examples for all four sources are depicted in Figure 3. With the exception of

Figure 3 A selection of sources used to generate radicals. (a) Pyrolysis. (b) Photolysis using a quartz tube. the chemical reactor, which constitutes an effusive source, they are coupled to pulsed valves and produce free jets of radicals.

3.2.1 Pyrolysis

In pyrolysis sources radicals are generated thermally from suitable precursors. In earlier experiments, vapor at low pressure was passed under effusive flow conditions through a heated tube into the apparatus.^{48,49} Secondary reactions, such as radical/radical recombination or the formation of unwanted side products were unavoidable. In the mid-1980s, a high-pressure flash pyrolysis source coupled with a supersonic expansion was introduced and largely solved these problems.⁵⁰ The design is depicted in Figure 3a. An electrically heated silicon carbide tube with a length of 10–20 mm and a diameter of 1 mm is mounted onto a molecular beam source with an orifice of 0.6–0.8 mm. A suitable precursor, diluted in 1–2 bar of a rare gas is expanded through this nozzle into the vacuum. In recent modifications of this design, water cooling was added for a more stable valve operation. Under these conditions a fast gas flow is achieved, which leads to short contact times with the heated wall on the order of some 10 μ s and reduces secondary reactions.⁵¹ In engineering terms, a pyrolysis source can be considered to be a

tubular flow reactor.⁵² A variety of radicals and carbenes have been generated by this method cleanly and in high number densities, hydrocarbon radicals in particular. Examples are alkyl radicals, $C_nH_{2n+1}^{\cdot}$,^{53–57} and unsaturated radicals with a conjugated π -system, such as $C_3H_3^{\cdot}$,⁵⁸ $C_3H_5^{\cdot}$,⁵⁹ benzyl ($C_7H_7^{\cdot}$),⁶⁰ and $C_9H_7^{\cdot}$ isomers.⁶¹ Also more exotic species such as the vinyl radical ($C_2H_3^{\cdot}$),⁶² benzyne,^{63,64} diazirine,⁶⁵ carbenes, that is, the various isomers of C_3H_2 ,^{66,67} the chlorophenyl carbene,⁶⁸ CF_2 ,⁶⁹ and other compounds have been successfully generated. Precursors often contain a carbon–halogen bond such as C–Br and C–I, but azo-compounds, diazirines, nitrites, and esters have also been employed. Precursors that yield N_2 as the side product are advantageous, because nitrogen does not interfere with most experimental schemes. A selection of pyrolytic routes to radicals and carbenes is depicted in Scheme 3. Often the precursors are themselves not very stable and have to be synthesized shortly before the experiments.

Flash pyrolysis has been successfully combined with a variety of spectroscopic techniques in all regions of the electromagnetic spectrum over the last couple of years, ranging from the microwave region⁷⁰ via infrared spectroscopy in both rare-gas matrices⁷¹ and free jets,⁷² electronic spectroscopy in the visible and in the UV^{53,73} to photoelectron spectroscopy with vacuum ultraviolet (VUV) radiation.⁷⁴ As described further below, it has

Scheme 3 Possible routes to the pyrolytic generation of radicals and carbenes.

also been employed in time-domain spectroscopy, photofragment and translational energy spectroscopy. Alternative designs,^{69,75} some of them relying on a longer contact time (≈ 1 ms),⁷⁶ are also used. Water cooling increases the stability of the pulsed valve at high pyrolysis temperatures,^{57,77} as depicted in Figure 3. Successful application in studies on small inorganic radicals has also been reported.⁷⁶

The selectivity of the method is demonstrated in Figure 4, using the generation of the indenyl radical, $\text{C}_9\text{H}_7\cdot$, by flash pyrolysis of 1-bromoindene as an example.⁶¹ Photoionization mass spectra utilizing VUV light at 8.5 eV were obtained with the pyrolysis source off (lower trace) and on (upper trace). As visible, the precursor is almost quantitatively converted and no side products (beside the Br atoms that cannot be ionized at this energy) are detected. In favorable cases radical densities of more than 10^{14} cm^{-3} can be achieved at the exit of the pyrolysis source.

3.2.2 Photolysis

The most common method for the generation of radicals is photolysis. It relies on the laser excitation of a precursor molecule to an electronic state that dissociates directly into the radical of interest plus a second fragment. For the generation of organic radicals, the corresponding iodides R-I are frequently used precursors because they are known to have dissociative states in the UV. These states can be populated by excitation with the fourth harmonic of a Nd:YAG laser at 266-nm or a 248-nm excimer laser. Photolysis can easily be coupled to supersonic beams by focusing the laser a few mm behind the pulsed valve orifice. The radicals will then be internally cooled in the subsequent expansion. An early example was the generation of CH_2 from ketene

Figure 4 Photoionization mass spectra of 1-bromoindene with pyrolysis off (lower trace) and on (upper trace), demonstrating the potential of a pyrolysis source. [Reproduced with permission from Ref. 61. Copyright 2010 American Chemical Society.]

using 337-nm radiation.⁷⁸ In a recent improvement, a quartz tube was attached to a pulsed valve to carry out the photolysis.⁷⁹ This setup is schematically depicted in Figure 3b. Reactive species such as $\text{NH}_2^\bullet$,⁸⁰ $\text{CH}_2^\bullet$,⁸¹ and even the elusive $\text{NH}_4^\bullet$ ⁸² have been generated photolytically in supersonically cooled jets. Allyl radicals with rotational temperatures of a few K have been obtained,^{83,84} a temperature that is lower than the one achieved in a pyrolysis source. Several peroxy radicals have been spectroscopically studied that are not accessible by other methods.⁸⁵ Sometimes the photolysis is carried out in the ionization region of a mass spectrometer and can then be coupled with an effusive source.^{86,87} In this case, hot radicals with a significant amount of internal energy can be investigated.

To obtain a sufficient photon flux for radical generation, a laser is required as the light source. This makes the technique more expensive than pyrolysis, but also more difficult because of the need for accurate synchronization. In addition, a single fixed-frequency photolysis laser is not enough to set up a general radical source. Although for many radicals good precursors exist (e.g., iodides) that dissociate upon 266-nm excitation, other radicals are not accessible at this wavelength. Thus a tunable system is required for a general photolysis source. On the other hand many radicals, in particular oxygen-containing species, have been successfully generated by photolysis that have not yet been produced by pyrolysis. Photolysis is commonly applied also in experiments studying bimolecular reactions (see Section 6).

3.2.3 Discharges

Electrical discharges are also frequently utilized for the generation of radicals. They can be coupled to supersonic jet sources, and radical yields are often quite good.⁸⁸ A common setup for a pulsed electric discharge, the so-called slit-jet discharge, is depicted in Figure 3c. Two electrodes, separated by a ceramics insulator, are mounted onto the pulsed valve.^{46,89} When the valve opens, and the molecules pass through the channel, the circuit is closed, a discharge occurs and the bonds in the precursor are cleaved. The slit jet is advantageous for use in absorption experiments because of the increased path lengths. Similar designs using

a circular channel with a diameter on the order of a millimeter have also been reported.^{90,91} Several halogen-containing species were successfully generated,^{90,92–94} but also allyl and ethyl radicals⁹⁵ as well as polyynes relevant to astrochemistry^{96–98} have been produced in this manner. A disadvantage of discharge sources is their lack of selectivity, typically with many side products being formed. On the other hand, they are a suitable source to generate thermochemically unfavorable radicals that are not available by other techniques. Since a pulsed discharge constitutes a low-temperature plasma, the source is well suited to study species relevant in plasma chemistry.

3.2.4 Chemical Methods

There is a large range of approaches to generate a desired radical by chemical reactions. Often abstraction of H-atoms by atomic fluorine, chlorine, or hydrogen is used. The reactive atoms are formed in discharges of the molecular dimer. A typical setup used in photoionization experiments⁴⁷ is depicted in Figure 3d. Dyke and coworkers utilized the abstraction of hydrogen from closed-shell molecules by fluorine atoms to produce radicals for photoelectron spectroscopy.^{99–102} This source works particularly well when all hydrogen atoms in the precursor are equivalent, for example, for alkyl radicals generated from alkanes. The technique has also been applied to produce Si-, Ge-, and N-containing radicals.^{103–105} Two interesting examples of H-atom abstraction by fluorine atoms pertain to species relevant in tropospheric chemistry: The $\text{O}_2\text{H}^\bullet$ radical was generated from H_2O_2 ¹⁰⁶ and $\text{NO}_3^\bullet$ from HNO_3 .¹⁰⁷ The latter is a night-time oxidant in the troposphere, where it is formed from $\text{NO}_2^\bullet + \text{O}_3$. An alternative way to produce $\text{NO}_3^\bullet$ in the laboratory is the reaction of HNO_3 with $\text{OH}^\bullet$, leading to $\text{NO}_3^\bullet + \text{H}_2\text{O}$.¹⁰⁸ Other atoms, such as $\text{Cl}^\bullet$ and $\text{H}^\bullet$, have been applied less often in such abstraction schemes: Cyclopentoxo radical was produced from cyclopentanol and photolytically generated chlorine atoms in a study of its unimolecular and bimolecular reactions.¹⁰⁹ A possible advantage of chlorine might be the better selectivity in H-atom abstractions. $\text{PH}_2^\bullet$ was generated in the reaction $\text{PH}_3 + \text{H}^\bullet$, that is, using hydrogen atoms in the abstraction step.¹¹⁰ A summary of the radicals that have been generated by chemical

reactions is given by Ruscic.⁴⁷ Although chemical methods are versatile, there are some disadvantages. For example, coupling to a supersonic expansion has not been achieved. However, there exist combinations of photolysis and chemical methods that allow a coupling with supersonic jets: The $\text{O}_3\text{H}^\bullet$ radical has been prepared by the reaction $\text{O}_2 + \text{OH}^\bullet$, the latter being formed in the photolysis of nitric acid in a jet.⁷

Metal-containing species can be obtained from laser vaporization.^{111,112} Originally, the method was applied to form metal clusters in a jet of rare gas. When organic compounds are admixed to the carrier gas, metal-containing radicals can be formed in the chemical reaction. Miller *et al.* showed that species such as $\text{CH}_3\text{M}^\bullet$ ($\text{M} = \text{Zn}, \text{Mg}$) could be studied.¹¹³ Species of the type MCH ($\text{M} = \text{Na}, \text{K}$) have been obtained from hot metal vapors^{114,115} and $\text{Na}_2\text{CN}^\bullet$ has been prepared in a sodium/NaCN metal/molecule mixture.¹¹⁶

There are more approaches to generate radicals. Shock tubes (see Section 6) are often used in bimolecular kinetics and can be considered to be in-between pyrolysis and a chemical reactor.

3.2.5 Neutralization–Reionization Mass Spectrometry

A rather specific, but widely applicable approach for the generation of radicals is based on mass

spectrometry. In this method, referred to as neutralization–reionization mass spectrometry (NRMS),¹¹⁷ an ionic precursor species is produced by any of the various mass-spectrometric ionization methods available, accelerated to a kiloelectronvolt kinetic energy, mass-selected, such that only the ion of interest enters the next step, and then neutralized in a collision with a stationary target gas (typically O_2 for the neutralization of anions and Xe for that of cations). The neutral species formed still has the incident kinetic energy in the kiloelectronvolt range and then enters a second collision cell in which it can be re-ionized to either anions or cations which are then detected by conventional mass-spectrometric means. The setup of such an NRMS experiment is shown in Figure 5.

NRMS is not restricted to radicals, but applicable to all ions which can be generated in yields sufficient for this kind of experiment; the neutralization–reionization (NR) yield is typically about 10^{-6} of the incident precursor ions. *Inter alia*, NRMS has also been used to generate and characterize several neutral biradicals.^{118–120} While the high-energy collisions involved pose several obstacles to the analysis of the data obtained, the main advantages of NRMS are that (i) ionic precursors can be used which can be prepared by selective ion/molecule reactions, (ii) the mass-selection steps avoids all possible problems arising from mixtures of species, and (iii) the existence of the neutral species can directly be probed experimentally. As an example, Figure 6 shows the NR mass spectrum of the allyloxide anion $\text{CH}_2 = \text{CH}-\text{CH}_2\text{O}^-$ with

Figure 5 Schematic illustration of a neutralization–reionization (NR) experiment: A mass-selected precursor ion $\text{M}^\pm$ is neutralized by electron transfer in a first collision cell C1, all remaining ionic species are deflected away, the fast beam of neutral species is reionized in a second collision cell C2, and the ions formed are mass-analyzed and detected. The resulting NR mass spectrum provides information about the existence of the neutral species M and about its dissociation into fragment ions $\text{F}^\pm$. The electron-transfer processes are driven by the kinetic energy of the incident beam and the resulting kinetic energy deficit (ΔE_{NR}) of the re-ionized species $\text{M}^\pm$ provides insight into the energetics of the redox reactions involved.

Figure 6 NR mass spectrum of mass-selected $\text{CH}_2=\text{CH}-\text{CH}_2\text{O}^-$ with reionization to cationic species. The “survivor signal” for intact $\text{C}_3\text{H}_5\text{O}^+$ demonstrates the intrinsic stability of the neutral radical. The various fragments signify the preferred dissociation channels via loss of hydrogen atom(s) as well as C–C bond cleavage to afford $\text{C}_2\text{H}_3^+ + \text{CH}_2\text{O}$ with subsequent fragmentations.

reionization to cations.¹²¹ The mere observation of a $\text{C}_3\text{H}_5\text{O}^+$ ion having the mass-to-charge (m/z) ratio of the anionic precursor demonstrates that the neutral allyloxy radical can survive for the time of flight between collision cells C1 and C2 (about 1 μs). The fragment ions observed provide insight into the dissociation of the neutral as well as the ionic species involved. It is interesting to note that NRMS has also been combined with pyrolytic radical generation.¹²²

As an extension to the NR method, a scheme referred to as NIDD (neutral-and-ion decomposition difference) has been introduced.¹²³ It allows to deconvolute the dissociation occurring at the neutral and ionic stages in cases in which the NR process is associated with a charge inversion (i.e., from cations to anions, $^+\text{NR}^-$, or from anions to cations, $^-\text{NR}^+$). In the case of methylamine, for example, the stepwise losses of either H-atoms or molecular H_2 toward the generation of HCN have been probed using the NIDD approach.¹²⁴ While the NR and NIDD approaches share the common drawback that the internal energies of the neutral species are not well defined, a compensation is provided by the mass-spectrometric steps before and after the NR sequence, which allows selection of certain target species from complex mixtures and likewise to study larger, more complicated radicals also including stereochemical features (see below).

4 PHOTOIONIZATION OF RADICALS

Photoionization techniques, associating mass spectrometry with well-defined and tunable sources of energy, are powerful tools to provide structural, energetic, and spectroscopic information on radicals $\text{R}^\bullet$ and their corresponding cations R^+ in the gas phase. This knowledge can be used in turn to probe the neutral radical dynamics by allowing the monitoring of either the reactant decay or the product appearance. Finally, photoionization is also a dedicated tool to produce R^+ cations with well-defined internal energy contents to study their unimolecular or bimolecular reactivity. In this section, we concentrate only on selected points related to the chemistry of $\text{R}^\bullet$ and R^+ on which this article is centered.

4.1 Photoionization: A Signature of the Radical

With the development of intense laser or SR sources, which are complementary in terms of resolution and tunability, studies of radical photoionization made large progress. Photoionization can be used to selectively probe radicals which are difficult to produce in large quantities and the yields of mass-selected ions as a function of photon energy provide detailed information specific for a certain

compound. The shape of the resulting curves, the onset above the radical ionization energy (IE), and possible structures in the spectrum revealing excitation between excited rovibronic states of the radical and the cations are a signature of a given radical. This can be used to identify products of unimolecular and bimolecular reactions as described in Sections 5 and 6, even in the case of isomers which appear at the same mass-to-charge ratio but can be distinguished by their photon energy dependence. Section 6, for example, describes how photoionization with tunable SR can serve as a multiplex detection method in setups that explore the kinetics of bimolecular reactions in chemical reactors and flames.

4.1.1 Ionization Energy and Franck–Condon Effects

The first aspect to be mentioned in the context of ionization of the radicals to the corresponding cations is that most radicals have relatively low IEs. It is a direct consequence of the underlying electronic structures that a radical (usually with doublet spin) upon ionization can *inter alia* yield a singlet species, which typically are quite stable. Hence the neutral state is a relatively energetic radical, whereas the ion state is some favorable closed-shell species, resulting in lower IE than, for example, an ionization of a neutral closed-shell molecule to the radical cation. For illustration, consider the ethyl radical for which the $\text{IE}(\text{C}_2\text{H}_5^\bullet) = 8.12 \text{ eV}$ ¹²⁵ is by more than 2 eV lower than those of its closed-shell congeners with $\text{IE}(\text{C}_2\text{H}_4) = 10.51 \text{ eV}$ ¹²⁵ and $\text{IE}(\text{C}_2\text{H}_6) = 11.52 \text{ eV}$.¹²⁵

The consequence of the low IE of radicals is that moderately energetic photons can induce their ionization. In laboratory experiments, only two or three UV photons in REMPI (resonance enhanced multi-photon ionization) schemes, and 7–12 eV VUV photons in a one-photon excitation scheme are sufficient to ionize most of the radicals. In some natural environments, such as interstellar medium or planetary ionospheres, the Lyman- α solar radiation ($\approx 10.2 \text{ eV}$) dominates the photon spectrum, and thus is sufficient to photoionize a large number of radical species.

Determinations of radical IEs have been conducted using standard methods¹²⁶ such as

photoionization (PI) yield analysis, photoelectron spectroscopy (PES), or threshold photoelectron spectroscopy (TPES) or pulsed field ionization technique (PFI) like zero kinetic energy spectroscopy (ZEKE)¹²⁷ with precision ranging from several tens of millielectronvolt down to a fraction of an inverse centimeter. Their description is outside the scope of this article.

Another important aspect to be discussed is that the ionization cross-sections of radicals often rise relatively slowly from the apparent threshold or even have an ill-defined shape. Upon first sight, this might appear quite surprising considering the low IE and one would hence expect a facile oxidation to the corresponding cation. However, the very same argument raised to explain the modest IEs of many organic radicals also accounts for the slowly rising ionization cross-sections in that the transitions between the neutral and the ionic states are not very efficient. As a measure for this efficiency, the related Franck–Condon factors (FCF) can be used, which describe the overlap of the wavefunctions of the initial state (neutral) and terminal state (cation). From a chemical point of view, FCFs can be correlated to the geometry differences between the initial and the terminal states. For similar equilibrium geometries (bond distances and angles), the FCF is good for the $(v_i, v_i^+) = (0, 0)$ transitions (v_i = vibrational quantum number for the v_i mode) and the ionization cross-section is large already at the ionization threshold. This behavior is found in the indenyl radical.⁶¹ Moreover, if the neutral radical and the cation have similar potential surfaces beyond the equilibrium geometries, the sequence bands associated with the diagonal transitions (1,1), (2,2), and so on will also show up nicely. On the other hand, if the geometries are similar, but the potential surfaces are not parallel, diagonal transitions (v_i, v_i) gradually decrease as a function of n and nondiagonal transitions $(0, v_i^+)$ will appear. This is the case for the methyl radical along the out-of-plane (umbrella) bending angle (v_2 mode). The radical $\text{CH}_3^\bullet$ and the cation CH_3^+ have similar planar structures at equilibrium, but the potential surface of $\text{CH}_3^\bullet$ is much more anharmonic along this coordinate than that of the cation. This results in a strong $(v_2, v_2^+) = (0, 0)$ band, lower (1,1) and (2,2) bands and a visible (0,2) band.^{128–130} Finally, if the geometries significantly differ, the FCF are poor for the lower states and only vibrationally excited states of the final state

Figure 7 Vertical and adiabatic redox transitions between the acetyl radical $\text{CH}_3\text{CO}^\bullet$ and the acetylium cation CH_3CO^+ .

can be produced efficiently. In the extreme case, the (0,0) transition may even not be detected at all and the ionization cross-section would instead start from some ill-defined point above $\text{IE}(\text{R}^\bullet)$. This is what happens for the $\text{CF}_3^\bullet$ radical and CF_3^+ cation,^{131–133} which have pyramidal C_{3v} and planar D_{3h} geometries, respectively. For the out-of-plane (umbrella) bending mode, the calculated FCF for the $(0, \nu^+)$ transitions is very low for small values of ν^+ and peaks at a much higher value of ν^+ around 20.¹³¹ Hence, the ion yield rises very slowly and the exact value of the adiabatic IE has been debated for a long time as reported by Botschwina *et al.*^{132,133}

To clarify this important aspect in the chemistry of radicals, let us consider the acetyl radical $\text{CH}_3\text{CO}^\bullet$ and the related acetylium ion CH_3CO^+ as an extreme and likewise illustrating case.¹³⁴ The acetyl radical is a carbon-centered σ -radical with the unpaired electron located in the CCO-plane. Repulsion of this electron with a doubly occupied $2p_\sigma$ orbital on oxygen leads to a bent situation of the CCO unit. Ionization via removal of the unpaired σ -electron leads to an acylium ion, having a linear CCO unit with pronounced resonance

stabilization and a formal sp-hybridization of the central carbon atom. While already the acetyl radical can in fact be considered as a reasonably stable species, the acetylium ion is even more stabilized and the associated *adiabatic* IE accordingly amounts to only $\text{IE}_a(\text{CH}_3\text{CO}^\bullet) = 7.10 \text{ eV}$ (Figure 7). Here, adiabatic means the transition from the optimal geometry of the neutral acetyl radical to the optimal structure of the cation, thus including a transition from a bent to a linear CCO unit. As removal of an electron in a typical ionization event is much faster than the movement of nuclei, the geometries often do not or only partially relax. FCFs can be used to express the corresponding transition moments for each rovibrational level. The extreme consideration is the neglect of any structural relaxation, hence a vertical transition. In this respect, the acetyl system is quite instructive. Thus, vertical ionization of the bent neutral radical leads to a situation in the cation state which cannot fully profit from resonance stabilization and the corresponding $\text{IE}_v = 8.65 \text{ eV}$ is significantly larger than $\text{IE}_a = 7.10 \text{ eV}$. Likewise, the vertical electron

Figure 8 Components in the vertical neutralization of the borinium cation B(OH)_2^+ to the neutral boryl radical $\text{B(OH)}_2^\bullet$ (energies in electronvolts). The transition from ① to ② is just the vertical recombination of the cation with an electron, from ② to ③ the angle α_{OBO} is relaxed for the neutral, while the points from ③ to the final minimum ⑥ include relaxation of the other degrees of freedom.

affinity of the acetylium ion, $EA_v = 5.60$ eV is more than 1 eV lower than $EA_a = IE_a = 7.10$ eV.

An even more extreme case in this respect is the neutralization of the closed-shell, main-group cation B(OH)_2^+ to the corresponding neutral radical.¹³⁵ In this particular example, the vertical electron affinity of the cation is almost 3 eV lower than the adiabatic value. Conventionally, once they think about the differences between vertical and adiabatic processes and the related Franck–Condon effects, chemists are trained to consider bond lengths as decisive properties while triangular or dihedral angles are given less importance. The deconvolution of the various contributions in the case of B(OH)_2^+ impressively demonstrates that this pragmatic simplification not always holds true (Figure 8). Thus, the most influential property in the vertical versus adiabatic electron affinity of B(OH)_2^+ is in fact the angle α_{OBO} whose change from 172° in the cation to 119° in the neutral species affects the cation's EA by almost 2 eV.

Advanced computational methods can also quantify the FCFs involved in ionization processes.^{51, 136–138} For a number of comparably small radicals or cases with a geometry change

limited to a few coordinates detailed simulations were carried out and can be performed with high accuracy as shown, for example, recently for the propargyl radical.¹³⁹ With some simplifications,¹⁴⁰ also more complicated photoionization processes such as in phenyl radical,¹⁴¹ metal-containing species,¹⁴² and toluene¹⁴³ can be simulated efficiently. But despite some approximations,¹⁴⁴ these methods are far from routine applications in the analysis of ionization thresholds. These limitations are to be kept in mind when evaluating the ionization thresholds of radicals in that the experimental uncertainties of data associated with low FCFs strictly speaking only lead to upper limits of the IEs, while the true adiabatic value could still be lower than the extracted value owing to particularly unfavorable FCFs.

4.1.2 Dissociative Photoionization

When the photon energy is higher than the dissociative photoionization thresholds, the radical photoionization contributes not only to the parent ion

yield but also to its fragment ion yield at lower masses by the processes $R^* + h\nu \rightarrow (R^+)^* + e^-$ and $(R^+)^* \rightarrow A^+ + B$. The parent and fragment yields have to be considered together to constitute the signature of a radical photoionization. The thermochemistry of the cation, and often in turn of the neutral radical itself, can also be derived from the measurements of appearance energies (AE) of the ionic fragments. The basic method described up to now, that is, ion yield measurements versus photon energy, is in principle the easiest way to proceed, but not the most precise, in particular because the photoelectron energy is not controlled. Much more reliable threshold energies can be derived from a careful analysis of the fragmentation diagram in experiments where the photoelectron energy is controlled, such as in threshold photoelectron-photoion coincidences (TPEPICO).¹⁴⁵ This technique not only provides valuable information on the radical or cation energetics, but is also used to study their unimolecular reactions and specifically the effect of the parent ion internal energy on its reactivity.

4.1.3 Absolute Photoionization Cross-Section

We have seen that relative photoionization cross-sections are useful signatures to identify radicals produced in reactions. It can also be helpful to know the absolute values of these photoionization cross-sections, in particular to derive branching ratio between reaction products or to quantify the concentration of a given species. Let us illustrate this aspect by reference to the photolysis of methane (CH_4) by VUV photons, which leads to various radicals in competitive channels: $CH_3^* + H^*$, $CH_2^* + H_2$, $CH_2 + 2 H^*$, or $CH^* + H_2 + H^*$. A precise knowledge of the branching ratio between these channels is very important for various environments, in particular for the Titan atmosphere, as methane photolysis is one of the starting steps for the radical chemistry. Surprisingly though, the branching ratio are not yet well determined and published values scatter over a large range as described by Gauyacq *et al.*^{146,147} Even if H-atom detection is very efficient, its exclusive use as a detection technique is not sufficient to extract the branching ratio because of overlaps between different channels. More precise data about the branching ratio are expected from the direct detection of CH_3^* , CH_2^* , and CH^* by photoionization. However, for the derivation of the branching

ratio, absolute photoionization cross-sections have to be determined first. Absolute photoionization cross-sections measurements for radical have been reported for methyl,^{146,148} ethyl,¹⁴⁹ vinyl, propargyl,¹⁵⁰ allyl, 2-propenyl,¹⁵¹ and phenyl.¹⁵² Usually, the methods used are based on the knowledge of a reference absolute photoionization cross-section (molecule A) and on the simultaneous measurements of two ion yields, A^+ and R^+ , where A and R^* are consumed or produced by the same process such as $A \rightarrow R^* + B$ or $B \rightarrow A + R^*$, B being a second molecule (or atom, respectively). In the case of the methyl radical for instance, pyrolysis of CH_3I leading to $CH_3^* + I^*$ has been used together with the reference absolute photoionization cross-section of CH_3I .¹⁴⁶ In this kind of experiment, great care has to be taken on the control of the relative detection efficiency of A^+ and R^+ . As absolute photoionization cross-section measurements are quite difficult and usually done with laser sources, they are often limited to selected photon energies. However, absolute values can be derived over a much larger range of photon energies by an additional and more simple experiment where only photoionization cross-sections relative to an absolute value obtained at a specific photon energy are measured with easily tunable radiation such as provided by a synchrotron source.^{146,148}

4.2 Photoionization of R^* Radicals as a Source of State-Selected Cations R^+

If one wants to study the reactivity of ground-state cations, there are several ways to produce cations by electron ionization or photoionization from various precursors and relax them to their vibrational ground state. However, if one wants to study the reactivity of polyatomic cations as a function of their internal energy (i.e., the vibrational quantum number), the only method at present is to produce the neutral radical R^* first, and use state-selection techniques such as TPEPICO described above to form the cation with a well-defined internal energy content. It has been demonstrated recently for the methyl case,¹²⁸ that the TPEPICO technique can be used to prepare the cation CH_3^+ from the neutral radical CH_3^* in a series of excited vibrational states corresponding to the symmetric out-of-plane (umbrella) bending mode, ν_2 . Experiments to study

the reactivity of the methyl cation as a function of its vibrational energy in an ion–molecule reaction setup are currently planned at Orsay.¹⁵³

5 UNIMOLECULAR REACTIONS

Unimolecular reactions of radicals, such as dissociation or isomerization reactions, are mostly studied using photoexcitation by a laser. This has the advantage that a well-defined amount of energy is deposited in the radical. The reaction products and rates of formation are then monitored at different excitation energies. Thermal rate constants necessary for combustion studies can easily be obtained from such data by convoluting them with the appropriate distribution functions. Studies of unimolecular reactions are focused on four central questions: (i) What are the reaction products? (ii) What is the reaction mechanism leading to those products? (iii) What are the time scales for the different steps involved in the reaction, that is, how long does each step take? (iv) How is the excess energy distributed among the product degrees of freedom?

The primary photophysical processes after excitation are best investigated by ultrafast spectroscopy.¹⁵⁴ It turns out that the lifetimes of excited electronic states in polyatomic radicals are generally

rather short. Since radicals often possess several low-lying excited electronic states, the spacings between them are small and the electronic couplings are large, so the excited states generally deactivate fast. The most suitable method is time-resolved photoionization, because charged particle detection is very sensitive and mass information is available. This is critical in experiments on species that are difficult to generate cleanly and at high number density. In the corresponding experiments, a first laser pulse (pump) excites the radical to the electronic state of interest, while a second pulse (probe) ionizes the radical. The delay between the two pulses is varied and either the ion- or photoelectron signal is monitored as a function of the delay time.¹⁵⁵

As an example, the time-resolved photoelectron spectrum of the *tert*-butyl radical recorded at pump-wavelengths of 324 nm is given in Figure 9.¹⁵⁶ This wavelength corresponds to excitation into the $A\ ^2A_1\ (3s)$ state. Two bands at different photoelectron kinetic energy are visible that grow in around the zero in time and decay quickly. The two bands correspond to different ionization processes: Although absorption of two photons at 810 nm is sufficient for ionization, most of the *tert*-butyl radicals absorb three photons. The maximum possible electron kinetic energy is depicted in Figure 9 as a dashed line. The

Figure 9 Femtosecond-time-resolved photoelectron spectrum of the *tert*-butyl radical.

Table 1 Lifetimes of excited electronic states for a number of reactive intermediates, as determined by ultrafast spectroscopy.

Intermediate	State	λ_{exc} (nm)	Lifetime	References
Ethyl, C_2H_5	$2^2\text{A}'$ (3s)	250	20 fs	157
Propargyl, C_3H_3	3^2B_1	255	50 fs	157
Allyl, C_3H_5	$\text{B } 2^2\text{A}_1$, $\text{C } 2^2\text{B}_1$	250–230	20–9 ps	158
<i>tert</i> -Butyl, $t\text{-C}_4\text{H}_9$	$\text{A } 2^2\text{A}_1$ (3s)	347–307	175–75 fs	156
	2^2E (3p)	268	2 ps	156
Hexyl, C_6H_{13} (2,3-dimethylbut-2-yl)	3p	265	25 fs/400 fs	159
Propadienylidene, $\text{l-C}_3\text{H}_2$	$\text{C } 1^1\text{A}_1$	250	70 fs	160
Benzyl, C_7H_7	4^2B_2	255	150 fs	157
	$\text{C } 2^2\text{A}_2$	305–298	400 fs/4.5 ps–180 fs/2.1 ps	60
Ph–C–Cl	$3^1\text{A}'$	267	40 fs/350 fs/1 ps	68

time-dependence is obtained from a cut through the two-dimensional plot at a given electron kinetic energy.

Table 1 summarizes results obtained for a number of radicals and two carbenes, chlorophenyl carbene, and propadienylidene. While some radicals have been investigated at a single wavelength only, others have been studied over a large range of excitation energies. For most radicals the excited-state lifetimes are on the order of a few picoseconds or less. An exception is allyl, which has a structured UV-spectrum that exhibits lifetimes of up to 20 ps for the origin of the B-state. In this context, it should be noted that several of the vibronic bands in allyl have been reassigned recently.⁸³ The lifetimes given in Table 1 correspond to the time for internal conversion (IC) to a lower electronic state. IC is the most important mechanism for excited-state deactivation in radicals. Intersystem crossing (ISC) does usually not occur, because quartet states are generally high in energy. For some species, more than one time constant is given, indicating a more complex dynamics. In these cases, we refer the reader to the original articles for more detailed discussions.

After IC, the radical ends up in the electronic ground state and electronic energy is converted to internal energy. The radicals may now possess enough energy to overcome the barrier to dissociation. In most radicals, this process takes place on the ground-state surface and occurs on a timescale between hundreds of picoseconds and several nanoseconds. It is the major task of the experimentalists to distinguish between the various possible reaction channels and to identify the most important reaction products. Since the reactions do not occur on an ultrafast time scale, ns-lasers are often sufficient. A common reaction pathway of

hydrocarbon radicals is the loss of a hydrogen atom, because a closed-shell molecule is formed. An excellent means to study this process is photofragment spectroscopy, as schematically depicted in Figure 10. A first laser promotes the radical into an excited electronic state that deactivates by IC to the electronic ground state. The energy is redistributed in the radical, and electronic excitation is converted to internal energy. In many radicals the amount of internal energy after IC is sufficiently high for a dissociation to occur. The H-atom product is then ionized by a second laser via the $1s\text{-}2p$

Figure 10 Description of photofragment spectroscopy. The radical is photoexcited in the UV by a first laser. After deactivation to the electronic ground state, the radical has enough internal energy to overcome the barrier to dissociation. One of the fragments is then detected by a second laser.

(Lyman- α) transition. Note that the ultrafast studies mentioned above monitor the first step (IC) indicated in Figure 10. Detection of the molecular fragment is also possible, but since it is formed in a range of rovibrational states, the signal from each individual transition is small and distributed over a large energy range. In contrast all H-atoms are formed in the 1s state and the oscillator strengths of the 1s $\rightarrow$ 2p transition is large, which makes H-atom detection extremely sensitive.

Three types of experiment are possible: (i) the delay between the lasers is varied to obtain reaction rates, (ii) the detection laser is scanned over the Doppler profile of the H-atom (accordingly, the method is also referred to as Doppler-spectroscopy) to get information on the H-atom reaction product, and (iii) the excitation energy is varied to get insight into the energy dependence of the processes. Figure 11 illustrates a type (ii) experiment, carried out on partially deuterated allyl radicals, excited at 248.15 nm (B 120¹). Only very few D-atoms are visible, thus the central C–H bond is preferentially broken. Therefore, the dominant reaction channel is the formation of allene¹⁶¹ and not propyne. An analysis of the profile of the H-atom signal reveals further details of the dissociation process.¹⁶²

The dissociation of numerous radicals has been studied by this method, including alkyl radicals such as ethyl,⁵⁴ 1- and 2-propyl,⁵⁷ *tert*-butyl,⁵⁶ and propargyl⁵⁸ as well as the carbenes 1-C₃H₂¹⁶³

Figure 11 The H/D-atom Doppler spectrum of partially deuterated allyl radicals shows that cleavage of the central C–H bond and formation of allene is the most important reaction channel.⁵⁹

and c-C₃H₂.⁶⁷ The method is well suited for light fragments being formed, for example, H[•] and D[•], but not well adapted to study C–C bond cleavage processes. An alternative technique is translational energy spectroscopy. Here fragmentation is also induced by a photon and the translational energy of the neutral reaction product is examined.¹⁶⁴ This method is well suited for investigating the products of a C–C bond cleavage. For example, the minor pathway in allyl photodissociation to CH₃[•] + C₂H₂ was examined using the technique,¹⁶⁵ but also the dissociation dynamics of the C₃H₅[•] isomers 1- and 2-propenyl.^{166–168} Some radical dissociations were investigated by both methods, among them the H-atom loss from propargyl at 248-nm excitation.^{58,169} Both methods yielded the same results.

For more complex radicals, the mass-spectrometric NR method (see Section 3.2.5) can provide valuable insight into the unimolecular rearrangement of transient radicals. In the case of alkoxy radicals, for example, electron detachment from the corresponding alkoxide ions provides a facile way for the generation of the neutral open-shell species. Using NRMS techniques, the fragmentation of a number of alkoxy radicals has been elucidated in quite some details and even stereochemical preferences in the dissociation of alkoxy radicals were derived from the mass-spectrometric studies (see Scheme 4 for an example).^{170,171}

Likewise, several carboxy radicals were probed using NRMS and similar hydrogen rearrangements involving the activation of C–H bonds remote from the functional group were observed in the case of aliphatic carboxylates.^{172–175} Further, these NR experiments could establish the existence of transient carboxy radicals beyond any doubt, even though decarboxylation according to reaction (8) is generally by about 0.5 eV exothermic.

In addition to these typical organic radicals, also several hypo- or hypervalent radicals involving main-group elements have been studied using NR methods, such as B(OH)₂[•],¹³⁵ CH₃BOH[•],¹⁷⁶ hypervalent ammonium radicals R₄N[•],^{177,178} and their oxygen analogs R₃O[•].^{179,180}

Scheme 4 Diastereoselective C–H(D) bond activation in the unimolecular rearrangement of neutral 3-methylpentoxy radicals formed via neutralization of the corresponding anions and probed via dissociative reionization of the rearranged species.

6 BIMOLECULAR REACTIONS

As discussed in a Section 2.1, modeling of combustion and plasma processes requires considerable knowledge on reaction rate constants¹⁹ under various conditions. Therefore, bimolecular reactions of many small molecules including radicals have been studied over a large range of pressures and temperatures using basically all of the radical generation techniques discussed in Section 3. Within the scope of this survey, only a selection of experiments can be discussed. High temperature data relevant for combustion kinetics have often been studied using shock tubes.^{181,182} Such devices consist of two compartments filled with gas, one at low pressure and one at high pressure, that are separated by a diaphragm. Once this diaphragm breaks, a shock wave travels through the low pressure gas and heats it up quickly. Reaction products are monitored by absorption or emission spectroscopy. A common light source for detecting atomic products is a microwave discharge lamp, but laser-based methods are also applied. According to Tsang and Lifshitz¹⁸¹ “a shock tube can be considered to be a millisecond high temperature furnace.” Typical temperatures that are studied range from 1000 to over 3000 K. Rate constants, activation energies, and Arrhenius parameters have been determined for the reactions of many hydrocarbons in particular with molecular oxygen. Different ways of radical generation are applied: Cyanonitrene, NCN was, for example, produced thermally from NCN₃ behind the shock wave,¹⁸³ but alternatively shock tubes have been combined with photolysis sources.¹⁸²

In many kinetics experiments, a radical is generated photolytically and reacts with a stable molecule in a suitable reactor. Either the decay of one of the reactants or the formation of a product is monitored by laser spectroscopic methods. Deriving rate constants from the data is straightforward because the time delay between two light sources can be easily varied. This approach works well when only a few species are involved that have a well-characterized electronic spectrum. However, in a complex reaction (a combustion process, for example) a wide variety of species is formed. Hence, there exists a need for the parallel detection of all products or at least most of them (multiplexing). In addition, a chemically selective detection is often required because in many cases several structural isomers of a given composition are conceivable. Simple mass-spectrometric detection is therefore not sufficient. Optical detection on the other hand suffers from the fact that the electronic spectra of larger radicals are often not known. The task to develop a method that permits to detect diluted species in an isomer-selective fashion has recently been accomplished using tunable synchrotron radiation (SR) as a light source for photoionization. SR has been combined with several setups for radical formation, a chemical reactor,¹⁸⁴ a flat flame burner^{5,21} and a plasma discharge.¹⁸⁵ In the chemical reactor,¹⁸⁴ a reaction mixture flows through a tube and a radical is generated photolytically. The reaction mixture (including the products) effuses through a small hole in the reactor and a subsequent sampling cone into the ionization region of a mass spectrometer. All components of the mixture are then continuously photoionized and detected in parallel. The zero in time is given by the photolysis

Figure 12 Example of a three-dimensional dataset, obtained in the SR-based product analysis of a flow reactor. It displays the reaction of ethyl radicals, produced by 193-nm photolysis of 3-pentanone, with O_2 . The three slices through the three-dimensional-plot show the photoionization efficiency as a function of reaction time for a given mass (right-hand vertical slice), the mass spectrum as a function of reaction time at a given photon energy (left-hand vertical slice), and the mass spectrum as a function of photon energy at a given time (horizontal slice).

laser. A key advantage of SR in this respect is its wide tuning range. By recording time delay traces over a large range of photon energies, the ionization onset of each component is observed, that is, the IE. Since the IE is characteristic for a given isomer, isomer selectivity is achieved. The experiment yields three-dimensional plots with the ion mass, the photon energy, and the reaction time delay plotted on the various axes. An example for the $C_2H_5 + O_2$ reaction²⁰ is given in Figure 12. Such a plot permits to assign reaction rates to a given isomer. Instead of a flow tube reactor, a flat flame burner can be used, permitting to identify the various intermediates formed during combustion as a function of the burner conditions.^{5,20,21} Several fuels have already been investigated. The plasma discharge experiments work in a similar manner, but radicals are generated in a discharge.¹⁸⁵ For experiments of this kind, it is helpful to know ionization and fragment AEs beforehand. Such data are sometimes available from the experiments described in Section 4, but when this is not the case, computed IEs can nowadays be relied upon quite well.^{186–189}

Bimolecular reaction rates are also important for astrochemistry,¹⁹⁰ as described in Section 2.4. However, here reliable rate constants are required at very low temperature, which is not possible with the approaches described above. In recent years, the so-called Cinétique de Réaction en Ecoulement Supersonique Uniforme (CRESU) technique¹⁹¹ proved to be successful in yielding low-temperature rate constants for bimolecular reactions of small radicals.^{190,192,193} In this technique, a mixture of reactant gases with a buffer gas (rare gas) is continuously expanded from a reservoir held at several 10 mbar through a Laval nozzle into the vacuum, adiabatically cooling the gas mixture to a few Kelvin. A Laval nozzle has an hour-glass shape and an opening diameter of 0.3–5 cm; therefore enormous pumping speeds are required in the experiments. The advantage of such an expansion lies in the well-defined temperature, which is constant over most parts of the beam. Different temperatures can be selected using different nozzles with varying geometries. Photolysis and detection laser are sent down axially with the expanding

Scheme 5 Reaction of the isomeric charged tagged phenyl radicals **A** and **B** with neutral methionine; branching ratios ($\Sigma = 100$) and overall reaction efficiencies (ϕ) are given on top of the respective arrows.

gas. Reactants or products are monitored by LIF. Rate constants have been obtained for a number of reactions of $\text{OH}^\bullet$, $\text{CN}^\bullet$, $\text{CH}^\bullet$, and other radicals with a variety of stable molecules such as H_2 , CO , O_2 , NO , as well as CH_4 and larger hydrocarbons. Rates have been determined for temperatures down to approximately 10 K. Recently, the technique was extended to reactions relevant to atmospheric chemistry,¹⁹⁴ in particular with regard to reactions of $\text{OH}^\bullet$ with volatile organic compounds (VOCs) that impact the chemistry of the troposphere.

Crossed beam techniques yield probably the most detailed insight into bimolecular reactions.^{195,196} In this technique, two reactants are expanded in separate molecular beams that cross in an ultrahigh vacuum and the products are analyzed in a mass spectrometer. Either the molecular beam sources or the mass spectrometer is rotatable so that the reaction products can be analyzed as a function of the scattering angle. Such experiments provide detailed insight into the reaction mechanism that is unmatched by any other method, but are very difficult to carry out. Nevertheless some groups reported studies on the reactions of small- and medium-sized radicals with stable molecules in crossed beams. Information on reactions in combustion,¹⁹⁷ planetary atmospheres,¹⁹⁸ and interstellar space¹⁹⁹ has been gained, and even reactions of hydrocarbon radicals with oxygen atoms (i.e., radical/radical reactions) have been studied.^{200,201}

Techniques based on mass spectrometry also have considerable potential for studying bimolecular reactions, in particular when larger molecules are involved. An interesting variant to investigate the bimolecular reactivity of radicals has been introduced by Kenttämä and coworkers, who applied charge tagging of neutral radicals. Charge tagging of the radical, that is introduction of an auxiliary

charge, ideally not interacting with the radical site, allows handling the so-formed ion radical by the rich repertoire of techniques in gas-phase ion chemistry. The concept is illustrated for the reactions of two aryl radicals with the amino acid methionine ($\text{CH}_3\text{SCH}_2\text{CH}_2\text{CH}(\text{NH}_2)\text{COOH}$).²⁰² The charged tagged radicals are generated from the corresponding iodides via collision-induced cleavage of the C–I bond, then mass-selected and allowed to interact with neutral amino acids. For the isomeric radical cations **A** and **B** in Scheme 5, a pronounced difference in reactivity has been found. Thus, radical **A** with the radical center in the same ring as the charge center predominantly reacts via abstraction of the thiomethoxy group and with a reaction efficiency (ϕ) of 75%; ϕ is the ratio of the overall reaction rate constant k_r and the gas-kinetic collision rate k_c and expresses the percentage of reactive collisions. In marked contrast, radical **B** reacts about three times slower and largely prefers H-atom abstraction.

The presence of a real Coulomb charge in this mass-spectrometric method makes it difficult to directly transfer the results to the respective reactions of the corresponding neutral radicals. However, it is obvious that with the other techniques presently available for the generation of neutral radicals and for the detection and analysis of the reaction products, complex open-shell systems such as **A** and **B** are rather difficult to tackle. Despite the perturbation introduced by the charge, the charge-tagging method is therefore a useful extension to the scope of methods for the investigation of radical reactivity and it has been applied to a number of different systems,^{203–205} including bi-²⁰⁶ and even triradicals.^{207,208} Also an example of a radical–radical reaction has been studied using this approach.²⁰⁹

7 CONCLUSIONS

Fundamental studies of isolated radicals in the gas-phase form an important basis for the understanding of radical reactions in general and for the evaluation of energetical aspects in particular. Furthermore isolated radicals dominate the chemistry of high-energy environments such as combustion engines, hydrocarbon crackers, plasmas, planetary atmospheres, and interstellar space. Especially photoionization studies of jet-cooled radicals can provide accurate benchmark data for the stability of radicals, which are important input parameters for the construction of more general reactivity models. It is to be recognized though that sometimes unfavorable Franck–Condon overlaps may prevent adiabatic ionization of neutral radicals into the corresponding ground-state cations. In addition to their value as such, accurate gas-phase experiments also provide benchmarks for the evaluation of contemporary theoretical methods for the description of open-shell compounds, which are of outmost importance in various areas of chemistry.

The high reactivity of most small radicals poses considerable challenges to the experimentalists. Not only are these species “unbottable” and tend to dimerize and/or dissociate, but often the conversion from the precursor compound to the desired radical(s) is incomplete such that interferences with the precursors can disturb the experiments. A pertinent task remains the selective generation of radicals in a controlled manner which is still a nontrivial task when it comes to more complex molecules. A number of methods exist to generate radicals efficiently that all have their particular strengths. However, there is no general method available for radical production. As far as unimolecular reactions of radicals are concerned, a large body of techniques has been developed which provide detailed insight into the decomposition mechanism of isolated open-shell compounds. Electronically excited states generally deactivate quickly, as shown by time-resolved photoionization using picosecond- and femtosecond-laser pulses. Further reactions often occur from the internally hot electronic ground state. Insight into the dissociation is obtained from techniques such as photofragment spectroscopy that yield information on the energetics of the reaction products. When combined with the mass-spectrometric techniques for the generation

and mass selection of suitable ionic precursors followed by neutralization, also rather complex molecular structures can be investigated in detail.

With regard to investigations of bimolecular reactions of radicals, several challenges emerge which are closely related to the difficulties in the production of free radicals: number densities are low, the high reactivity may lead to reactions with impurities and interferences with precursor molecules may critically disturb the quantitative analysis of the data. In this respect, photoionization with synchrotron ionization is a promising technique that permits to study numerous reaction components in parallel and thus offers the multiplex advantage. In mass spectrometry-based techniques, the charge-tagging method developed by Kentämaa is a useful step forward, although the perturbation introduced by the presence of a real Coulomb charge in ionic species is not negligible.

Considering the significant progress in both radical preparation and detection techniques, further advances are expected in the future. An increased knowledge into radical chemistry will in turn improve our understanding of technologically relevant reactions systems, such as combustion engines or low-temperature plasmas.

ACKNOWLEDGMENTS

This study was supported by the Academy of Sciences of the Czech Republic (Z40550506), the Deutsche Forschungsgemeinschaft (Fi575/3-x 7-x and 8-1), the RTRA “triangle de la physique” (project “Radicaux” 2009-007T) and the European Research Council (AdG HORIZOMS). We would like to thank Dr. Taatjes (Sandia lab) for providing us with Figure 12.

Radical Stability—Thermochemical Aspects

Johnny Hioe and Hendrik Zipse

Department of Chemistry, LMU München, München, Germany

1 INTRODUCTION

The terms “transient” and “persistent” are used frequently in the scientific literature to describe the kinetic properties of open shell systems in homogeneous solution.^{1–5} The hydroxyl radical (HO•, **1**), for example, is a *transient* species of central importance in atmospheric chemistry (see **Atmospheric Radical Chemistry**), as well as one of the most important reactive oxygen species (ROS) in aqueous solution, whereas the nitroxide 2,2,6,6-tetramethylpiperidine-1-oxyl, TEMPO (**2**) is a persistent radical stable enough to be bottled and sold in bulk (Figure 1) (see **Nitroxides in Synthetic Radical Chemistry**).

However, despite their widespread use, these terms are not too helpful for a quantitative approach to radical chemistry as they do not reflect the influence of thermochemical driving force and intrinsic reaction barrier on the observed lifetime. In this account, we assemble a large amount of thermodynamic data for (mostly neutral) open shell systems to provide a foundation for a quantitative discussion of reactivity. This type of data will, for example, show that reactions of radical **1** are typically much more exothermic than those of radical **2**. Thermodynamic data for open shell systems can be computed with comparable ease for stable as well as for unstable systems, while the experimental determination of quantities such as the heat of formation of a particular radical

is quite challenging. Kinetic data, in contrast, are much more difficult to predict by theory, while the determination of reaction rates can be approached experimentally with a variety of direct or indirect methods, at least for sufficiently fast reactions (see **Radical Kinetics and Clocks**). Theory and experiment pair up nicely in this respect, as a combination of these approaches is able to provide a comprehensive picture of thermodynamic and kinetic data.

2 DEFINITIONS OF RADICAL STABILITY

The thermodynamic stability of C-centered radicals can be defined in various ways and several options are discussed in the following.^{6–10} One of the most often used definitions is based on hydrogen transfer reactions as shown in Scheme 1 for reaction of methyl radical (•CH₃, **3**) with hydrocarbon R¹R²R³C–H.^{6,9,11,12}

$$\begin{aligned} \text{RSE}(\text{R}^1\text{R}^2\text{R}^3\text{C}^\bullet) &= \Delta H_{298}(\text{R}^1\text{R}^2\text{R}^3\text{C}^\bullet) \\ &+ \Delta H_{298}(\text{CH}_4) \\ &- \Delta H_{298}(\text{R}^1\text{R}^2\text{R}^3\text{C}-\text{H}) \\ &- \Delta H_{298}(\text{CH}_3^\bullet) \end{aligned} \quad (1a)$$

$$\begin{aligned} \text{RSE}(\text{R}^1\text{R}^2\text{R}^3\text{C}^\bullet) &= \text{BDE}(\text{R}^1\text{R}^2\text{R}^3\text{C}-\text{H}) \\ &- \text{BDE}(\text{CH}_3-\text{H}) \end{aligned} \quad (1b)$$

Figure 1 Hydroxyl radical **1** and 2,2,6,6-tetramethylpiperidine-1-oxyl radical (TEMPO) **2**.

The reaction energy of the reaction in Scheme 1 is often referred to as the radical stabilization energy (RSE) of radical $R^\bullet$ and is, of course, identical to the difference in homolytic C–H bond energies in the two closed shell systems $\text{CH}_3\text{--H}$ (**3H**) and $R\text{--H}$. The RSE value of $R^\bullet$ can thus equally well be expressed by (1a) or by (1b) and is negative for systems more stable than the methyl radical $^\bullet\text{CH}_3$ (**3**). Expression (1b) makes it also clear that theoretically calculated and experimentally measured bond dissociation energy (BDE) data can conveniently be combined to express the stability of radicals in a quantitative way. Using the above definition, the stability of *tert*-butyl radical ($((\text{CH}_3)_3\text{C}^\bullet$, **4**) amounts to $-38.9 \pm 2.9 \text{ kJ mol}^{-1}$ when using experimentally measured heats of formation¹³ or to $-29.1 \pm 0.7 \text{ kJ mol}^{-1}$ using energies derived from G3-level calculations (Table 1). Whether these values are due

to stabilizing interactions between the unpaired spin and the three methyl substituents in radical (**4**) or whether this also reflects other components such as steric strain in the closed shell reference system isobutane (**4H**) cannot be seen from the results in Table 1. For further discussion of alternative approaches to defining radical stability, we also include here data for hydroxymethyl radical (**5**) and fluoromethyl radical (**6**). The C–H bond energies in methanol (**5H**) and fluoromethane (**6H**) are smaller than that in methane (**3H**), implying a stabilizing influence of HO- and F-substituents on the radical center according to (1).

From a conceptional point of view, it is also important to note that (1) is an isodesmic reaction, which is defined as a reaction with retention of the number of bonds of a given formal type.^{15,16} This implies that RSE values can be computed quite accurately even with moderately accurate quantum mechanical methods (Table 1). Alternative definitions to characterize the stability of carbon-centered radicals in a quantitative way have been proposed, which circumvent the cleavage of C–H bonds.^{14,17–19} This involves the cleavage of a fully apolar C–C bond in the formal dimer of the respective radicals. Using again the methyl radical as a (nonstabilized) reference system and accounting for

Scheme 1 Isodesmic hydrogen transfer reaction defining the RSE of C-centered radicals.

Table 1 RSE values for *tert*-butyl radical ($((\text{CH}_3)_3\text{C}^\bullet$, **4**), hydroxymethyl radical ($^\bullet\text{CH}_2\text{OH}$, **5**), and fluoromethyl radical ($^\bullet\text{CH}_2\text{F}$, **6**) calculated according to (1).

	Method	RSE (kJ mol ⁻¹)
$^\bullet\text{C}(\text{CH}_3)_3$ (4)	Exp. ^a	-38.9 ± 2.9^{13}
	G3	-28.4
	G3B3	-29.8
	G3(MP2)-RAD	-28.5
$^\bullet\text{CH}_2\text{OH}$ (5)	Exp. ^a	-37.4 ± 0.6^{13}
	G3B3	-33.5
	G3(MP2)-RAD	-32.3
	Exp. ^a	-15.5 ± 4.2^{13}
$^\bullet\text{CH}_2\text{F}$ (6)	G3B3	-13.4
	G3(MP2)-RAD	-12.8

^aThe following experimentally measured BDE values (see Ref. 13) have been used to calculate RSE values: $\text{BDE}(\text{CH}_3\text{--H}) = +439.3 \pm 0.4 \text{ kJ mol}^{-1}$; $\text{BDE}((\text{CH}_3)_3\text{C--H}) = +400.4 \pm 2.9 \text{ kJ mol}^{-1}$; $\text{BDE}(\text{FCH}_2\text{--H}) = +423.8 \pm 4.2 \text{ kJ mol}^{-1}$; $\text{BDE}(\text{HOCH}_2\text{--H}) = +401.9 \pm 0.6 \text{ kJ mol}^{-1}$.

the fact that two radicals are generated simultaneously in this process leads to (2) as the defining equation (Table 2).

$$\text{RSE}(\text{R}^1\text{R}^2\text{R}^3\text{C}^\bullet) = 0.5[\text{BDE}(\text{R}^1\text{R}^2\text{R}^3\text{C}-\text{CR}^1\text{R}^2\text{R}^3) - \text{BDE}(\text{CH}_3-\text{CH}_3)] \quad (2)$$

While this definition avoids most of the pitfalls of using the C–H BDE process presented first, it also does have its own problems. These are mainly connected to cases, in which the two halves of the symmetric dimer reference system interact through more than just the central covalent bond. For the dimer of *tert*-butyl radical (**4**) we may, for example, assume the presence of steric interactions, whose relief on C–C bond dissociation will artificially stabilize radical **4**. Two additional cases worthy of consideration are ethylene glycol ($\text{HOCH}_2\text{CH}_2\text{OH}$), whose cleavage leads to hydroxymethyl radical ($\text{CH}_2\text{OH}^\bullet$, **5**), and 1,2-difluoromethane ($\text{FCH}_2\text{CH}_2\text{F}$), whose cleavage generates the fluoromethyl radical ($\text{CH}_2\text{F}^\bullet$, **6**). In the first of these systems, the two halves communicate through an internal hydrogen bond and additional stereoelectronic effects, while in the second example only the latter aspect remains. This leads in both of these systems to a preference for gauche conformations. The magnitude of the gauche effect in 1,2-difluoroethane can be quantified through the gauche/anti enthalpy difference as -1.8 kJ mol^{-1} at G3(MP2)-RAD level, in

close proximity to previous estimates.^{20–22} RSE values calculated according to (2) therefore, need to be corrected for these additional interactions to extract the true substituent effect on radical stability.^{14, 17–19} Following the approach pioneered by Zavitsas *et al.*, this leads to corrected RSE values of $\text{RSE}_Z((\text{CH}_3)_3\text{C}^\bullet, \text{4}) = -5.1 \text{ kJ mol}^{-1}$, $\text{RSE}_Z(\text{CH}_2\text{OH}^\bullet, \text{5}) = -8.5 \text{ kJ mol}^{-1}$, and $\text{RSE}_Z(\text{CH}_2\text{F}^\bullet, \text{6}) = +13.7 \text{ kJ mol}^{-1}$ (Table 2). In contrast to the results obtained from (1), this implies that fluorine substituents directly attached to the radical center are destabilizing. A third way of quantifying radical stability involves the cleavage of a C–C bond in a nonsymmetric reference compound^{14, 17–19}:

$$\text{RSE}(\text{R}^1\text{R}^2\text{R}^3\text{C}^\bullet) = \text{BDE}(\text{R}^1\text{R}^2\text{R}^3\text{C}-\text{CH}_3) - \text{BDE}(\text{CH}_3-\text{CH}_3) \quad (3)$$

This definition solves a number of problems arising from steric or stereoelectronic interactions in the symmetric reference compounds discussed above. Without addition of any correction terms, this leads to the results shown in Table 3. For all three systems considered here, the RSE values obtained from (3) are very close to the RSE_Z values resulting from the combination of (2) with the correction terms proposed by Zavitsas.¹⁴

The defining equation (1) for measuring stabilities of carbon-centered radicals can be adapted

Table 2 RSE values for *tert*-butyl radical ($(\text{CH}_3)_3\text{C}^\bullet$, **4**), hydroxymethyl radical ($\text{CH}_2\text{OH}^\bullet$, **5**), and fluoromethyl radical ($\text{CH}_2\text{F}^\bullet$, **6**) according to (2).

^a The following experimentally measured BDE values (see Ref. 13) have been used to calculate RSE values: BDE(CH₃-CH₃) = +377.4 ± 0.8 kJ mol⁻¹; BDE((CH₃)₃C-CH₃) = +363.6 ± 2.9 kJ mol⁻¹; BDE(HOCH₂-CH₃) = +364.8 ± 4.2 kJ mol⁻¹; BDE(FCH₂-CH₃) = +388.3 ± 8.4 kJ mol⁻¹.

**Scheme 2** Isodesmic H-atom transfer reactions defining the RSE of S-, O-, and N-centered radicals.

to determine the stability of sulfur-, oxygen-, and nitrogen-centered radicals in a straightforward fashion by adjusting the reference systems to the corresponding radical type (Scheme 2).

How radicals respond to the presence of a particular substituent depends largely on the electronegativity of the atom holding the unpaired spin. This can be exemplified with the effects of the methyl substituent on the stability of C-, S-, O-, and N-centered radicals (Table 4). The RSE values calculated for ethyl radical ([•]CH₂CH₃, **9**) and for methylthiyl radical ([•]SCH₃, **10**) are moderately large with -18.8 and -15.5 kJ mol⁻¹, respectively, and thus illustrate the stabilizing effect of this substitution on the respective reference systems. A larger effect of RSE(**11**) = -25.0 kJ mol⁻¹ is obtained for the methylaminy radical ([•]NHCH₃, **11**), and a much larger stabilizing effect of -56.9 kJ mol⁻¹ is obtained for methyloxy radical ([•]OCH₃, **12**).

The rather different substituent effects calculated for O- and C-centered radicals raise the question of how to characterize the stability of resonance-delocalized radicals involving heteroatoms in the π -system. This is discussed using the enoxy radical **13** as an example, which can either be viewed as a C-centered or as an O-centered radical. Attempting to formulate the corresponding isodesmic equation for the stability of such a resonance-delocalized system, it becomes apparent that there is only one (fully delocalized) radical, but that there are two different closed shell reference systems (Scheme 3). Formal hydrogen transfer between acetaldehyde (**13H(C)**) and methyl radical (**3**) generates enoxy radical **13** and methane (**3H**). The Lewis structure **13a** is shown to reflect the fact that hydrogen abstraction occurred from the C2 atom. This reaction is exothermic by -36.7 kJ mol⁻¹ at G3(MP2)-RAD

at DFT level with subsequent single point calculations using a wavefunction-based method. The most economical of these approaches uses RMP2 single point calculations in combination with the 6-311+G(3df,2p) basis set.³¹ Results obtained with this approach are typically as good as with the best DFT methods, but show some systematic weaknesses in the description of strongly spin-delocalized systems.²⁹ These can, in part, be overcome through combination of correlation energies calculated with density functional and perturbation theory methods as is, for example, employed in the B2-PLYP approach.^{32–34} A notable and systematic improvement in accuracy is obtained when combining large basis set RMP2 calculations with small basis set RCCSD(T) calculations as is done in the G3(MP2)-RAD scheme developed by Radom *et al.*^{35–37} This compound scheme is largely similar to the G3(MP2)B3 method proposed by Curtiss *et al.*,^{24–26} but uses restricted open shell reference wavefunctions for MP2 and CCSD(T) calculations. Owing to a good price/performance ratio, this model has developed into one of the most frequently used methods for accurate predictions of radical thermochemistry in recent years.^{6–9,14,27–29,38} Benchmark studies using a test set of smaller radicals indicate that heats of formation can be predicted with an accuracy of around 5 kJ mol^{−1} with this model. Even better predictions (albeit at a significantly higher price) with an accuracy of around 3 kJ mol^{−1} can be obtained with the G3B3 compound scheme

or its radical-optimized variant G3-RAD.^{35–37} Even more accurate predictions can be obtained using one of the members of the Weizman-n family of methods such as “W1” or selected variations of *Gaussian-4* (G4) theory.^{32,39–43} But the applicability of these methods even to medium-sized systems provides a formidable technical challenge and these approaches will thus be mainly employed for benchmark purposes.³⁸ All RSE values cited in the following text have been calculated at G3(MP2)-RAD level, if not mentioned otherwise.

4 THE STABILITY OF CARBON-CENTERED RADICALS

4.1 The Stability of Monosubstituted C-Centered Radicals

Substituent effects on the stability of alkyl radicals can be classified in three categories: (A) stabilization through resonance effects; (B) stabilization through lone-pair donation; and (C) stabilization through hyperconjugative effects. The resonance-stabilized radicals in group A are among the most stable C-centered radicals, and allyl radical **14** and benzyl radical **15** can be considered to be typical examples. As shown in Figure 2, the unpaired spin is delocalized in these systems over large parts of

Figure 2 Radicals stabilized through resonance effects (**14**, **15**), through lone-pair donation (**16**), and through hyperconjugation (**9**).

the attached π -system, leading not only to large stabilization energies of $\text{RSE}(\mathbf{14}) = -72.0 \text{ kJ mol}^{-1}$ and $\text{RSE}(\mathbf{15}) = -61.0 \text{ kJ mol}^{-1}$ (Table 5), but also to some challenges in accurate quantum mechanical calculations (see Ref. 7 for a detailed discussion).

Experimentally measured $\text{BDE}(\text{C-H})$ values for methane (**3H**), propene (**14H**), and toluene (**15H**) imply a similarly small difference between radicals **14** and **15** with $\text{RSE}(\mathbf{14})_{\text{exp}} = -67.7 \pm 1.7 \text{ kJ mol}^{-1}$ and $\text{RSE}(\mathbf{15})_{\text{exp}} = -63.6 \pm 2.9 \text{ kJ mol}^{-1}$.⁴⁴

^a Taken from Ref. 13 if not specified otherwise.^b Taken from Ref. 44.^c Taken from Ref. 45.^d Taken from Ref. 46.

The stability of heteroallylic radicals depends systematically on the number and electronegativity of the heteroatoms in the π -system. As a consequence, the allyl radical **14** is much more stable than iminylmethyl radical $\cdot\text{CH}_2\text{C}(\text{NCH}_3)\text{H}$ (**17**) with $\text{RSE}(\mathbf{17}) = -43.5 \text{ kJ mol}^{-1}$, enoxy radical $\cdot\text{CH}_2\text{CHO}$ (**13a**) with $\text{RSE}(\mathbf{13a}) = -36.7 \text{ kJ mol}^{-1}$, methyl acetate radical $\cdot\text{CH}_2\text{C}(\text{O})\text{OCH}_3$ (**18**) with $\text{RSE}(\mathbf{18}) = -23.2 \text{ kJ mol}^{-1}$, and nitromethyl radical $\cdot\text{CH}_2\text{NO}_2$ (**19**) with $\text{RSE}(\mathbf{19}) = -12.4 \text{ kJ mol}^{-1}$. Inspection of the RSE values for monosubstituted alkyl radicals in Table 5 also shows that resonance-stabilized radicals of propargyl type such as radical $\cdot\text{CH}_2\text{CCH}$ (**20**) with $\text{RSE}(\mathbf{20}) = -52.8 \text{ kJ mol}^{-1}$ are less stable than allyl radicals with otherwise comparable substitution pattern. The dimethylaminomethyl radical **16** is a typical representative of group **B**, in which lone-pair donor atoms are directly attached to the radical center. The stabilizing effects of these types of substituents can most easily be described through admixture of Lewis structure **16b**, which derives from the canonical structure **16a** through effective one electron transfer from the heteroatom lone pair to the radical center (Figure 2). Considering the nature of this type of stabilization, it is not surprising to see again a clear effect of the electronegativity of the heteroatom on the size of the stabilization energy. Radical **16** with $\text{RSE}(\mathbf{16}) = -46.1 \text{ kJ mol}^{-1}$ is thus significantly more stable than methoxymethyl radical $\cdot\text{CH}_2\text{OCH}_3$ (**21**) with $\text{RSE}(\mathbf{21}) = -31.5 \text{ kJ mol}^{-1}$ and the fluoromethyl radical $\cdot\text{CH}_2\text{F}$ (**6**) with $\text{RSE}(\mathbf{6}) = -12.8 \text{ kJ mol}^{-1}$. Moving from first to second row elements as substituents also increases radical stability in many cases as is, for example, seen in the larger stability of radical $\cdot\text{CH}_2\text{SCH}_3$ (**22**) with $\text{RSE}(\mathbf{22}) = -41.0 \text{ kJ mol}^{-1}$ as compared to methoxymethyl radical $\cdot\text{CH}_2\text{OCH}_3$ (**21**). Ethyl radical $\cdot\text{CH}_2\text{CH}_3$ (**9**) is a representative of group **C**, in which radical stabilization occurs through interaction of the unpaired spin with adjacent C–H and C–C bonds. This is traditionally portrayed through mixing the canonical Lewis structure **9a** with the “no bond” Lewis structure **9b** (Figure 2). These effects are rather moderate and stabilize ethyl radical **9** by $\text{RSE}(\mathbf{9}) = -13.5 \text{ kJ mol}^{-1}$. Replacing the β -C–H bonds in radical **9** by C–C bonds leads to a small, but notable reduction in radical stability as is readily seen when comparing radical **9** to *n*-propyl radical $\cdot\text{CH}_2\text{CH}_2\text{CH}_3$ (**23**) with

$\text{RSE}(\mathbf{23}) = -12.2 \text{ kJ mol}^{-1}$, 2-methylprop-1-yl radical $\cdot\text{CH}_2\text{CH}(\text{CH}_3)_2$ (**24**) with $\text{RSE}(\mathbf{24}) = -10.6 \text{ kJ mol}^{-1}$ and 2,2-dimethylprop-1-yl radical $\cdot\text{CH}_2\text{C}(\text{CH}_3)_3$ (**25**) with $\text{RSE}(\mathbf{25}) = -7.1 \text{ kJ mol}^{-1}$. Strained C–C bonds as are, for example, present in cyclopropylmethyl radical $\cdot\text{CH}_2\text{CH}(\text{CH}_2)_2$ (**26**) are much stronger interaction partners in hyperconjugative interactions and thus lead to larger stabilization energies of $\text{RSE}(\mathbf{26}) = -23.4 \text{ kJ mol}^{-1}$. The introduction of electron-withdrawing substituents in β -position to the radical center is always destabilizing as is readily seen in the low stability values for 2-fluoroethyl radical (**27**) with $\text{RSE}(\mathbf{27}) = -5.8 \text{ kJ mol}^{-1}$ and 2,2,2-trifluoroethyl radical (**28**) with $\text{RSE}(\mathbf{28}) = +8.0 \text{ kJ mol}^{-1}$. This subgroup also includes C5'-desoxyadenosyl radical ($\cdot\text{Ado}$, **29**) with $\text{RSE}(\mathbf{29}) = -6.8 \text{ kJ mol}^{-1}$, whose stability parallels that of other primary alkyl radicals carrying a β -hydroxy substituent such as ethanol-2-yl radical **30** with $\text{RSE}(\mathbf{30}) = -10.3 \text{ kJ mol}^{-1}$ (Figure 3).^{6,8} This value implies that the adenosine π -system present in radical **29** has only little influence on its thermodynamic stability. Generated through either a thermal process from cofactor B_{12} or through a redox process from *S*-adenosylmethionine (SAM), radical **29** plays a central role in many enzymatic processes employing radical chemistry for substrate turnover (see **Radical Enzymes**).^{47–51}

4.2 The Stability of Di- and Trisubstituted Alkyl Radicals

In more highly substituted alkyl radicals, the interplay of substituents attached to the radical center usually leads to more strongly stabilized radicals (that is, weaker C–H bonds in the respective closed shell parent systems). The actual stability obtained in a highly substituted system is, however, rarely a simple function of the individual substituents (Tables 6 and 7).⁵² This can be exemplified with the textbook examples of methyl radical $\cdot\text{CH}_3$ (**3**), ethyl radical $\cdot\text{CH}_2\text{CH}_3$ (**9**), isopropyl radical $\cdot\text{CH}(\text{CH}_3)_2$ (**31**), and *t*-butyl radical $\cdot\text{C}(\text{CH}_3)_3$ (**4**). The stabilities of these four systems are not equally spaced in the sense that the stabilizing effect of the first methyl group equals that of the second and third addition. Instead of being additive, each further addition of a methyl group leads to a smaller

Figure 3 Graphical representation of RSE values for monosubstituted radicals together with the C–H BDE values of the corresponding closed shell parent systems.

change in radical stabilization as can easily be seen from the actual stability values of $\text{RSE}(\mathbf{9}) = -13.5 \text{ kJ mol}^{-1}$, $\text{RSE}(\mathbf{31}) = -23.0 \text{ kJ mol}^{-1}$, and $\text{RSE}(\mathbf{4}) = -28.5 \text{ kJ mol}^{-1}$. This type of saturation behavior⁵³ on repeated addition of the same substituent is also observed for more strongly interacting substituents. Addition of a second phenyl substituent to the already quite stable benzyl radical $\cdot\text{CH}_2\text{Ph}$ (**15**) with $\text{RSE}(\mathbf{15}) = -61.0 \text{ kJ mol}^{-1}$ yields benzhydryl radical $\cdot\text{CH}(\text{Ph})_2$ (**32**), whose stability value of $\text{RSE}(\mathbf{32}) = -85.5 \text{ kJ mol}^{-1}$ is far smaller than expected from a simplistic additivity assumption. The multiple addition of electronegative substituents carrying lone-pair electrons leads to yet another behavior that can be best illustrated with the three fluorinated methyl radicals $\cdot\text{CH}_2\text{F}$ (**6**), $\cdot\text{CHF}_2$ (**33**), and $\cdot\text{CF}_3$ (**34**). The stability of these systems is heavily influenced by stereoelectronic effects among the C–F bonds in both the

open shell systems and in the respective closed shell parents.⁵⁴ This is not yet apparent in fluoromethyl radical ($\cdot\text{CH}_2\text{F}$, **6**), whose RSE value of $-12.8 \text{ kJ mol}^{-1}$ can be taken to reflect mainly the effect of the fluorine substituent on the radical center and on the C–H bonds in the closed shell parent. In the radicals with more than one fluorine atom per carbon, however, the donor–acceptor interactions between lone-pair (lp) electrons on fluorine and the adjacent $\sigma^*(\text{C–F})$ bonds now alter the apparent RSE values in a significant manner. This can be exemplified by inspection of the isodesmic equation (9) used for defining the stability of $\cdot\text{CF}_3$ (**34**), whose evaluation at G3(MP2)-RAD level yields $\text{RSE}(\mathbf{34}) = +13.1 \text{ kJ mol}^{-1}$ (Table 7, Scheme 4).

Radical **34** as well as its closed shell parent **34H** are characterized by several simultaneously acting donor/acceptor interactions (Scheme 4). The size

Table 6 Radical stabilization enthalpies (RSE, in kJ mol⁻¹) at 298.15 K of disubstituted methyl radicals and C–H bond dissociation energies of the respective closed shell compounds calculated according to (1).

of these stereoelectronic effects can be assessed separately for the closed and the open shell systems using (10a) and (10b). Using these definitions and heats of formation for all species from experiment, we obtain an overall anomeric stabilization of CHF₃ (**34H**) of –135.7 kJ mol^{–1} and for radical *CF₃ (**34**) of –84.2 kJ mol^{–1}. These values imply that the stereoelectronic effects among the fluorine substituents in closed shell system CHF₃ (**34H**) are significantly larger than those in the corresponding

radical *CF₃ (**34**). The reaction energy for (9) initially used to define the stability of radical **34** is thus more a reflection of changes in stereoelectronic effects among the fluorine substituents than an indicator of the interaction of the unpaired spin with its direct surrounding!

One of the cases where synergistic substituent effects are observed in highly substituted alkyl radicals are donor/acceptor-substituted systems.^{53,55,56} The glycol radical **35** is often discussed as a typical

and is also important example owing to its high stability^{57–61} and its involvement in enzymatic catalysis (Figure 4).^{6,8,47–50}

The radical center is here flanked on one side by a carbonylamino substituent and on the other side by a aminocarbonyl substituent. The individual effects of these substituents can be quantified by donor-substituted radical **36** with RSE(**36**) = –43.0 kJ mol^{–1} and acceptor-substituted radical **37** with RSE(**37**) = –23.1 kJ mol^{–1}. If these effects were additive, we may expect radical **35** to be quite

stable with a stabilization energy of –66.1 kJ/mol relative to methyl radical **3**. The stabilization energy actually calculated for radical **35** at G3(MP2)-RAD level is RSE(**35**) = –74.1 kJ mol^{–1}, 8 kJ mol^{–1} more than the sum of the individual effects. This increase is commonly rationalized by donor/acceptor (or “captodative”) interactions between the two substituents as expressed by Lewis structure **35b**.

In how far the electronic substituent effects discussed for singly substituted alkyl radicals can act on the radical center is also determined by

Scheme 4 Isodesmic equations to define the stability of radical **34** and the size of stereoelectronic effects in trifluoromethane **34H** and radical **34**.

Figure 4 Donor/acceptor-substituted glycol radical **35**, the donor-substituted radical **36**, and the acceptor-substituted radical **37**.

steric effects or other geometrical constraints. This is particularly relevant for radicals in small ring systems, where the orientations of substituents are strictly controlled by ring geometry. In addition, the size of RSE values of cyclic radicals may also reflect changes in ring strain energies between the radical and its closed shell parent. The stability of cycloalkyl radicals of various ring sizes as calculated at G3 level are collected in Figure 5 together with the RSE value for the isopropyl radical (**31**) as the acyclic reference system.

The very low stability of cyclopropyl radical **38** with $\text{RSE}(\mathbf{38}) = +13.1 \text{ kJ mol}^{-1}$ is mainly a reflection of differences in ring strain between cyclopropane (**38H**) and radical **38** and implies, that the C–H bonds in cyclopropane (**38H**) are stronger than in methane (**3H**). These effects are diminished, but still present in cyclobutyl radical (**39**) with $\text{RSE}(\mathbf{39}) = -15.1 \text{ kJ mol}^{-1}$. The

stability of cyclopentyl radical **40** at $\text{RSE}(\mathbf{40}) = -33.0 \text{ kJ mol}^{-1}$ is actually larger than that of the acyclic isopropyl radical **31**, whose stability at G3 level amounts to $\text{RSE}(\mathbf{31}) = -22.2 \text{ kJ mol}^{-1}$, while the stability of cyclohexyl radical **41** is almost identical to this acyclic reference system at $\text{RSE}(\mathbf{41}) = -20.0 \text{ kJ mol}^{-1}$ (Figure 6).

4.3 The Stability of Other C-Centered Radicals

A larger number of C-centered radicals exist in which the formal radical center is bound to only two neighbors. This is the case for all radicals, which are at least formally generated through hydrogen atom abstraction from C(sp²) hybridized carbon atoms and the term *σ-type radicals* is frequently used to reflect this point. The stability of these systems can be defined as before relative to the methyl radical/methane reference pair using hydrogen transfer reaction (11) (Scheme 5, Table 8).

Figure 6 Graphical representation of RSE values for di- and trisubstituted alkyl radicals together with the C–H BDE values of the corresponding closed shell parent systems.

Scheme 5 Hydrogen transfer reaction used to define the stability of σ -type C-radicals.

Even though (11) is not an isodesmic reaction anymore, it allows for the direct comparison with all other C-centered radicals. Vinyl radical (**42**) and phenyl radical (**43**) are two of the best-known systems from this class. Using the definition in (11) both system are highly destabilized relative to methyl radical **3** with $\text{RSE}(\mathbf{42}) = +26.0 \text{ kJ mol}^{-1}$ and $\text{RSE}(\mathbf{43}) = +37.0 \text{ kJ mol}^{-1}$, thus reflecting the much larger C–H BDEs in ethylene and benzene as compared to methane. Large stabilizing effects are observed in this class of radicals when the doubly bonded substituents R^2 are heteroatoms carrying lone-pair electrons. As a consequence the C–H bond

energies in formic acid derivatives and aldehydes are significantly smaller than those in methane. An example in case is radical **44** derived from benzaldehyde with $\text{RSE}(\mathbf{44}) = -52.4 \text{ kJ mol}^{-1}$ (Figure 7).

5 THE STABILITY OF SULFUR-CENTERED RADICALS

Aliphatic and aromatic thiols are effective hydrogen atom donors owing to the comparatively weak S–H bond in these compounds. This is evident already for the smallest thiol H₂S (**7H**) with BDE(S–H) = +381.2 kJ mol^{-1} , 58.1 kJ mol^{-1} less than the C–H BDE value in methane (Table 9).¹³ The introduction of alkyl or aryl substituents leads to a further reduction of the S–H BDE as is readily seen in the stability values of the resulting thiyl radicals (Table 9). Alkyl substituents influence the stability of thiyl radicals in a similar way as is observed for alkyl

radicals. A point in case is methylthiyl radical **10** with RSE(**10**) = −18.1 kJ mol^{-1} , which represents a slightly larger effect than is observed for ethyl radical **9** with RSE(**9**) = −13.5 kJ mol^{-1} . An interesting system from this group is cysteinyl radical **45** with RSE(**45**) = −13.7 kJ mol^{-1} obtained through hydrogen abstraction from the thiol side chain of cysteine diamide **45H** (see structure in Figure 12).⁸ Cysteine radicals play a central role in many radical enzymes, where they are directly involved in substrate turnover. A recent comparison of radicals involved in enzymatic catalysis has shown that the stability of these radicals hardly differ from those of simple alkyl thiyl radicals such as **10**.⁸ A more

^a Taken from Ref. 13 if not specified otherwise.^b Taken from Ref. 8.^c Taken from Ref. 62.^d Taken from Ref. 63.^e Taken from Ref. 64.**Figure 8** Resonance stabilization of phenylthiyl radical (46).

strongly stabilized thiyl radical is obtained in the presence of aromatic substituents as in thiophenyl radical **46** with $\text{RSE}(\mathbf{46}) = -43.6 \text{ kJ mol}^{-1}$ because of extensive delocalization of the unpaired spin (Figure 8).

In contrast to benzyl radical **15**, however, the stability of phenylthiyl radical (**46**) is significantly influenced by the presence of substituents in *para* position of the aromatic ring system. While the presence of acceptor substituents as in nitro-substituted radical **47** leads to lower RSE values ($\text{RSE}(\mathbf{47}) = -35.1 \text{ kJ mol}^{-1}$), a significant enhancement of stability is achieved through donor-substituents as in amino-substituted radical **48** ($\text{RSE}(\mathbf{48}) = -57.6 \text{ kJ mol}^{-1}$). The oxidation of thiols to sulfenic acids (RS(O)H) and sulfinic acids ($\text{RS(O)}_2\text{H}$) leads to a strong reduction in S–H bond strength, making both compound classes interesting as antioxidants.^{65–67} These compounds can exist in O- and S-tautomeric forms, the former of which is significantly more stable (Figure 9). The corresponding BDE values are therefore discussed in the following section on O-centered radicals.

6 THE STABILITY OF OXYGEN-CENTERED RADICALS

The stability of oxygen-centered radicals depends much more strongly on the substitution pattern than is the case for carbon- or sulfur-centered radicals of otherwise comparable structure. The reference point for the definition of radical stability in (5) is in this case given by H_2O with its rather strong O–H bond ($\text{BDE}(\text{O–H}) = +497.1 \text{ kJ mol}^{-1}$, Table 10). Since the performance of the G3(MP2)-RAD method for O-centered radicals is less satisfactory than for other radical classes, the following discussion is based on results obtained at the (higher) G3B3 level. The $\cdot\text{OH}$ radical can be stabilized quite effectively through alkyl groups as is apparent from the stability value for methoxy radical $\cdot\text{OCH}_3$ (**12**) with $\text{RSE}(\mathbf{12}) = -55.7 \text{ kJ mol}^{-1}$. Even more stable radicals are obtained in the presence of aromatic substituents and the value of the *para*-methylphenoxy radical with $\text{RSE}(\mathbf{49}) = -129.4 \text{ kJ mol}^{-1}$ may be typical here. These very high stability values imply rather low O–H BDE values in the respective

closed shell phenols, many of which are known to have antioxidative properties. Previous studies on borane/water and borane/alcohol complexes also indicate that O–H bond energies are substantially lower in these complexes as compared to the free protic compounds.⁶⁸ Nitroxide radicals derived through hydrogen abstraction from hydroxylamines represent another class of very stable O-centered radicals. Even the smallest of these systems $\cdot\text{ONH}_2$ (**50**) is strongly stabilized with $\text{RSE}(\text{50}) = -164.6 \text{ kJ mol}^{-1}$. The “persistent” TEMPO radical **2** thus derives its lack of reactivity from both a high thermodynamic stability as well as substantial steric hindrance. The

previously discussed oxidation products of thiols such as methylsulfenic acid **52H** and methylsulfinic acid **51H** are known to exhibit S/O-tautomerism (Figure 9). Both theoretical and experimental studies on these compounds have shown that the respective O-tautomers (**51bH** and **52bH**) predominate over the S-tautomers (**51aH** and **52aH**). Using enthalpies obtained at G3B3 level indicates that tautomer **52aH** is 51.0 kJ mol^{-1} less stable than tautomer **52bH**.

Hydrogen atom abstraction from either of these tautomeric forms yields the same open shell species **51** and **52**, in which the unpaired spin is delocalized over the S and O atoms. The stabilities

Figure 9 Tautomeric forms of methylsulfinic acid (**51H**) and methylsulfenic acid (**52H**) together with the corresponding sulfinyl radical **51** and sulfenyl radical **52** formed after hydrogen abstraction.

of the radicals relative to the O-protonated tautomeric forms ($\text{RSE}(\mathbf{51}) = -162.2 \text{ kJ mol}^{-1}$ and $\text{RSE}(\mathbf{52}) = -205.3 \text{ kJ mol}^{-1}$) are indicative of the highly stabilized nature of these radicals and the correspondingly weak O–H bonds in the precursor sulfenic and sulfinic acids.

7 THE STABILITY OF NITROGEN-CENTERED RADICALS

The homolytic N–H BDE in NH_3 (**8H**) of $+450.1 \pm 0.24 \text{ kJ mol}^{-1}$ (Table 11) indicates a slightly stronger bond than the C–H bond in methane. Despite this similarity, the substituent

effects observed for N-centered radicals can be distinctly different as compared to those seen for C-centered radicals. Alkyl substitution is strongly stabilizing as in primary aminyl radical **11** with $\text{RSE}(\mathbf{11}) = -30.0 \text{ kJ mol}^{-1}$. The addition of a second alkyl group as in secondary aminyl radical **53** is slightly less effective with $\text{RSE}(\mathbf{53}) = -52.6 \text{ kJ mol}^{-1}$, showing the saturation behavior already noted for C-centered radicals. Single and double phenyl substituents as in *N*-phenylaminyl radical **54** and *N,N*-diphenylaminyl radical **55** also show slightly larger stabilities than is seen in the analogous C-centered radicals. Surprisingly, acceptor substituents such as carbonyl groups have a clearly destabilizing effect on aminyl radicals, leading to rather strong N–H bonds in amide groups. A comparison of stability values for aminyl radicals with different acceptor substituents such as formyl-substituted radical **56** with $\text{RSE}(\mathbf{56}) = +28.8 \text{ kJ mol}^{-1}$, acetyl-substituted radical **57** with $\text{RSE}(\mathbf{57}) = +22.1 \text{ kJ mol}^{-1}$, or urea-derived radical **58** with $\text{RSE}(\mathbf{58}) = +5.2 \text{ kJ mol}^{-1}$ also indicates a stronger destabilization for systems carrying more strongly electron-withdrawing substituents. Analysis of the wavefunction of these systems reveals the existence of two close lying electronic states, an energetically preferred state of *A''* symmetry

Figure 10 Different electronic states for aminyl radical **56**.

and a higher lying state of A' symmetry (assuming a C_s symmetric structure for both states).^{59, 73–75}

The orbital occupations in these two states can approximately be described with the cartoons shown in Figure 10. In the energetically less favorable A' state, the nitrogen lone-pair electrons are localized in a p-type atomic orbital optimally aligned for resonance delocalization into the adjacent C–O double bond. At the same time, this leaves the unpaired electron in an orbital oriented orthogonally to the C–O π -systems and thus unable to attain the stabilization available in other heteroallylic radicals. In the energetically more favorable A'' state, the orbital occupations at nitrogen are interchanged, now allowing for resonance delocalization of the unpaired electron into the C–O π -systems. This now leaves the nitrogen lone-pair electrons in the orbital oriented orthogonally to the C–O π -systems and thus unable to attain the stabilization available in the parent amide systems. It is this loss of resonance delocalization of the nitrogen lone-pair electrons that ultimately leads to the low stability of radical **56**.

8 THE STABILITY OF BORON-CENTERED RADICALS

The stability of boron-centered radicals is a key factor in rationalizing the properties of boranes as

hydrogen atom donors^{38, 77–80} and as reagents in transition-metal-mediated reactions.^{81, 82} In analogy to other open shell systems discussed before a quantitative definition of the stability of boryl radicals can be given using isodesmic equation (12a). For boranes complexed to Lewis bases this takes on the form of (12b) (Scheme 6).

However, in remarkable contrast to the systems discussed before, the B–H BDE in the reference borane BH_3 (**59H**) seems not to be well established. The single experimental study on the heat of formation of BH_2 radical **59** implies a BDE(B–H) value of $+312 \text{ kJ mol}^{-1}$, more than 100 kJ mol^{-1} less than found by most theoretical studies.^{13, 38, 81–83} Benchmark-quality calculations at W4.3 level put the B–H bond energy in BH_3 at $+441.14 \text{ kJ mol}^{-1}$, a value in close proximity to the C–H bond energy in methane (CH_4). This value is, in the following, used to quantify radical stability according to (12a, 12b). While the effect of alkyl substituents attached to the boron atom on the B–H bond energies is quite moderate, the complexation of boranes to Lewis bases leads to large changes in B–H bond energies. Even weakly coordinating Lewis bases such as amines and phosphanes lead to a significant stabilization of boryl radicals as can be seen from the stability values for borane complexes $H_2B^*NH_3$ (**60**) and $H_2B^*PH_3$ (**61**) with $RSE(\mathbf{60}) = -13.7 \text{ kJ mol}^{-1}$ and $RSE(\mathbf{61}) = -54.3 \text{ kJ mol}^{-1}$, respectively (Table 12). Significantly lower BDE(B–H) values and thus more stable boryl radicals are obtained through complexation with Lewis bases including a π -system. This is readily seen for boryl radicals **62** and **63** with stability values of $RSE(\mathbf{62}) = -112.5 \text{ kJ mol}^{-1}$ and $RSE(\mathbf{63}) = -116.3 \text{ kJ mol}^{-1}$. The spin density distribution is in these cases not well described with

Scheme 6 Hydrogen transfer reactions used to define the stability of boryl radicals.

^aG3(MP2)-RAD//MPW1K/6-31+G(d).^bTaken from Ref. 13.^cValue obtained at W4.3 level of theory as taken from Ref. 38.^dTaken from Ref. 81, 82.

the canonical Lewis structures in Table 12 as substantial parts of the unpaired spin density are delocalized into the adjacent π system. The most stable boryl radicals are obtained through complexation to carbonyl groups as in radical **64** with $\text{RSE}(\mathbf{64}) = -184.0 \text{ kJ mol}^{-1}$. The unpaired spin density is in this system localized almost exclusively on the carbonyl carbon atom and radical **64** should, therefore, best be seen as a borylketyl radical (Figure 11).

9 RELATIVE STABILITY SCALES FOR C-, S-, O-, N-, AND B-CENTERED RADICALS

The equivalence of differences in RSE and differences in BDE mentioned before provides a basis for the comparison of stability values for radicals of different type. This is shown

graphically in Figure 12, in which the origins of all individual stability scales are anchored onto a global (absolute) BDE scale. The strongest bond in the reference systems is the O–H bond in water (**1H**) with $\text{BDE}(\text{O–H}) = +497.1 \text{ kJ mol}^{-1}$, followed by the N–H bond in ammonia (**8H**) with $\text{BDE}(\text{N–H}) = +450.1 \text{ kJ mol}^{-1}$, the B–H bond in borane (**59H**) with $\text{BDE}(\text{B–H}) = +441.1 \text{ kJ mol}^{-1}$, the C–H bond in methane (**3H**) with $\text{BDE}(\text{C–H}) = +439.3 \text{ kJ mol}^{-1}$, and the S–H bond in H_2S (**7H**) with $\text{BDE}(\text{S–H}) = +381.2 \text{ kJ mol}^{-1}$. This implies, for example, that the origin of the O-radical scale is shifted to the origin of the C-radical scale by 57.8 kJ mol^{-1} to higher energies. A direct comparison of radicals of different type is most easily accomplished by combination of the (experimentally measured) BDE values for the reference systems with the (theoretically calculated) RSE

Figure 11 Graphical representation of the Lewis-base-boryl-radical stability at G3(MP2)-RAD//MPW1K/6-31+G(d) level of theory.

Figure 12 Relative stability scales for C-, S-, O-, N-, and B-centered radicals.

values of a particular radical. The strength of the central C–H bond in 2-methylpropane ((CH₃)₃C–H, **4H**), for example, can be calculated through combination of the RSE value for *tert*-butyl radical (**4**) of RSE(**4**) = –28.5 kJ mol^{–1} with the C–H BDE in methane (**3H**) of BDE(C–H) = +439.3 kJ mol^{–1} to give BDE(C–H, **4H**) = 439.3 – 28.5 = +410.8 kJ mol^{–1}. In a completely analogous way, the BDE(O–H) value in 4-methylphenol (**49H**) can be calculated as BDE(O–H, **49H**) = 497.1 – 129.4 = +367.7 kJ mol^{–1}, and the BDE(N–H) value in aniline (**54H**) can be calculated as BDE(N–H, **54H**) = 450.1 – 65.7 kJ mol^{–1} = +384.4 kJ mol^{–1}. These values imply that hydrogen abstraction through *tert*-butyl radical (**4**) from 4-methylphenol (**49H**) is exothermic by $\Delta H_{298} = 367.7 - 410.8 \text{ kJ mol}^{-1} = -43.1 \text{ kJ mol}^{-1}$ and from aniline (**54H**) is exothermic by $\Delta H_{298} = 384.4 - 410.8 \text{ kJ mol}^{-1} = -26.4 \text{ kJ mol}^{-1}$. These two examples illustrate the fact that the radicals shown in the global stability scale in Figure 12 can be converted from the left to the right side in an exothermic fashion using the appropriate hydrogen transfer reactions. One striking result of this type of global stability comparison is the largely similar stability of tyrosyl radical (**71**), glycyl radical (**35**), and cysteinyl radical (**45**), three amino acid-derived radicals of outstanding importance in enzymatic catalysis. One additional advantage of the combined RSE/BDE scales in Figure 12 is the ease of combination of theoretically calculated and experimentally measured BDE values. Tin hydride H–SnBu₃ (see **Tin Hydrides and Functional Group Transformations**) and silane H–Si(SiMe₃)₃ (see **Silanes as Reducing Reagents in Radical Chemistry**), for example, have experimentally determined X–H BDE values of BDE(Sn–H) = +328.9 kJ mol^{–1} and BDE(Si–H) = +351.5 kJ mol^{–1}, respectively.^{84,85} Using the data derived above for *tert*-butyl radical (**4**), these values imply that reaction of radical **4** with these hydrogen donors is exothermic by $328.9 - 410.8 \text{ kJ mol}^{-1} = -81.9 \text{ kJ mol}^{-1}$ (HSnBu₃) or by $351.5 - 410.9 \text{ kJ mol}^{-1} = -59.4 \text{ kJ mol}^{-1}$ (HSi(SiMe₃)₃).

10 CONCLUSIONS

The stabilities of a variety of radicals can be determined quantitatively using reaction energies for

hydrogen transfer reactions with an appropriately selected reference system. Despite the fact that this definition is, to a certain extent, arbitrary and that the obtained stability values may not always reflect substituent effects on the unpaired spin alone, the resulting energies are nevertheless helpful owing to the flexibility of this type of definition and the wide occurrence of hydrogen transfer reactions in open shell systems. One particular strength of this type of thermodynamic data is the possibility to predict exothermic and endothermic processes with equal accuracy, and the facile combination of experimentally measured and theoretically calculated data.

Free Radical Chemistry in Room-Temperature Ionic Liquids

Ilya A. Shkrob¹ and James F. Wishart²

¹Chemical Sciences and Engineering Division, Argonne National Laboratory, Argonne, IL, USA
and ²Chemistry Department, Brookhaven National Laboratory, Upton, NY, USA

1 INTRODUCTION

Room-temperature ionic liquids (ILs) are fascinating new solvents consisting of oddly shaped organic cations and organic or inorganic ions.^{1,2} These compounds bridge the divide between molecular liquids and ionic solids. Some of the typical ions that are used in the synthesis of ILs are shown in Scheme 1. Owing to the irregular shapes of the constituting organic cations (such as alkyl-substituted ammonium, phosphonium, pyrrolidinium, morpholinium, pyridinium, imidazolium, and other cations), the melting points of these ionic compounds are often below room temperature. Although their characteristics can vary over a tremendous range, ILs generally possess low volatility, good electric conductivity, moderate to high viscosity, and microheterogeneity that produces different local environments favoring simultaneous solubility of polar and nonpolar compounds.³ Since the development of air- and water-stable ILs, the field has exploded and the present and potential applications of these new solvents have increased exponentially.^{1,2,4} These applications presently span the whole range of synthetic and industrial chemistry: from electrolytes in oxide-based solar cells¹ to extraction solvents in spent nuclear fuel processing^{5,6} to cellulose extraction and chemical processing⁷ to the control of organosynthetic reactions⁸ to a Moon telescope,⁹ just to name a few such possible applications. It

has been realized that ILs may constitute the largest class of organic liquids, because the number of combinations of the possible cations and anions is astronomical. As such, to exhaustively review free radical behavior in ILs would be comparable in scope to reviewing this behavior in all of molecular liquids that are presently known. Furthermore, as any radical that can be generated in a molecular liquid can also be generated in ILs, the potential scope of such a review would be limitless. The common methods for production of organic radicals, such as thermolysis, photolytic cleavage, electron transfer, electrochemistry, introduction of chemically stable radicals (such as FeCl_4^{-10} and superoxide anion¹¹), or the use of spin traps for converting short-lived reaction intermediates to stable radicals—all of such methods have been realized in ILs. However, providing a comprehensive list of such radicals in the ILs would be impractical and beyond the scope of this review. Instead, we present some examples of how radical solutes have been used to probe the properties of ILs and how ILs influence radical reactivity, but we focus primarily on the radicals derived from ILs themselves, and their reactivity.

To date, the most investigated class of ILs contain 1-methyl-3-alkylimidazolium cations (C_Nmim^+ , where N is the carbon number for the alkyl chain in the long arm, Scheme 1 for $X = \text{H}$) and the corresponding 2-alkyl derivatives (e.g., $X = \text{Me}$).

Scheme 1 Typical constituent ions in room-temperature ionic liquids. (a) “Aliphatic cations”: alkylated ammonium and phosphonium, pyrrolidinium, piperidinium, and morpholinium cations. (b) Alkylated imidazolium (X = H, Me) and pyridinium cations (“aromatic cations”) and dicyanamide and bistriflimide (NTf₂⁻) anions.

For such cations, we shall adopt a nomenclature in which the residue of the imidazolium cation with respect to substitution in the n -th atom in the ring (Scheme 1) is designated as Q_n . In this nomenclature, the 2-imidazolyl radical is $Q_2H^\bullet$, the N -heterocyclic carbene (NHC) is $Q_2^{2\bullet}$, and so on.

The solvation and dynamics of radical intermediates and spin probes in ILs have been frequent subjects of studies.^{12–24} Such experiments go back to the pioneering work of Noel, Allendoerfer, and Osteryoung,¹² who used electron paramagnetic resonance (EPR) spectroscopy to study the rotational dynamics of nitroxide radicals in the mixtures of C₂mim Cl and AlCl₄. Detailed studies of rotational dynamics of neutral and charged stable nitroxide radicals aiming to determine the microviscosity of the IL have been reported. An elegant application of this method by Compton's group at Oxford was the recent demonstration of viscosity reduction when hydrophobic C₂mim NTf₂ (Scheme 1) was saturated by SO₂ and CO₂.²⁴ Another study used methylviologen radical cation (MV²⁺) to estimate the rates of diffusion-controlled electron self-exchange with MV²⁺, thus investigating translational rather than rotational dynamics.²¹ A somewhat similar method was used to study the effect of ILs on the conformational dynamics of stable biradicals through the exchange interaction between the termini bearing the unpaired electrons.^{22,23} The drawback of such studies is that the inferences of molecular detail in the solute–solvent and solvent–solvent interactions are indirect and often qualitative. In this sense, the current realizations of the method may provide less insight than ultrafast laser studies reviewed elsewhere.^{25–27}

In general, the rotational and translational dynamics in ILs tend to be slow^{12–21} owing to their generally higher viscosity and strong solute–solvent interactions, and these features have significant effects on charge separation and charge recombination dynamics.²⁸ Such properties of the ILs can be exploited for macromolecular synthesis involving (living) radical and ionic polymerization^{29–33} and catalysis,^{34,35} which was quickly realized following the discovery of air- and water-stable ILs. The classical example of such reactions are Cu(I)- N -propyl-2-pyridylmethanimine-mediated living radical polymerization of methyl methacrylate³⁶ and radical C–C cyclizations induced by Mn(III)(OAc)₃.³⁷ One-electron redox reactions of aromatic molecules in imidazolium ILs, whether chemical or electrochemical, are very facile and the resulting radical ions are stabilized by π – π solute–solvent interactions.^{38–43} Among such reactions, halogen anion elimination shows very strong solvent effects as compared to common polar solvents (such as acetonitrile).^{38,40,44} Normally, the solvation of the leaving halide anion disfavors cleavage via the entropy term. As the ILs are composed of bulky cations, this term is much lower in the ILs.³⁸ This is the fairly common theme in the chemistry of radical intermediate in the ILs: the strength of the solvent–solute interactions is modulated by steric and crowding effects in such ILs.

Some methods of free radical generation, however, are more peculiar to the ILs and closely related to the structure of the constituent ions. These methods include radiolysis,^{45–52} photoionization and photoinduced charge separation involving the excited constituent ions,⁵³ and electrochemical breakdown of neat ILs.^{54–58} A more exotic radical chemistry is possible for imidazolium ILs. The cation ($C^+ = Q_2H^+$) easily deprotonates from 2-position in the presence of weak bases and the resulting carbene $Q_2^{2\bullet}$ (2-ylidene) can react with H⁺ atoms or muonium (Mu), μ^+e^- (the heavy “isotope” of H⁺), yielding 2-(Mu)-imidazolyl radicals

observed by muon spin resonance spectroscopy.^{59–61} A recent example of this method is the attachment of the muonium to the dimer form of the carbene, $(Q_2)_2$ (also known as the *electron-rich olefin* or the *symmetric dimer*) to produce the corresponding dimer radical $Q_2(Q_2H)^\bullet$

(Scheme 2), which can also be produced in a reduction of C_N mim $Cl-AlCl_3$ by metallic lithium. The electron-rich olefin is the product of the Lemal (equilibrium) reactions well known in NHC chemistry⁶²: the carbene attaches to the C(2) position of the parent cation and the resulting “asymmetric dimer” $Q_2(Q_2H)^+$ cation reacts with another carbene, yielding the symmetric dimer and recovering the parent cation:

($Q_2Ar^{\cdot}$, where Ar is an aryl group) are produced through photoinduced N–C bond cleavage of *o*-chlorohexaarylbisimidazole (*o*-Cl-HABI). Normally radical–radical reactions are diffusion limited, but the recombination of lophyl radicals is typically slow in molecular solvents ($k_{\text{rec}} = 300\text{--}8000\text{ M}^{-1}\text{ s}^{-1}$)⁶⁵ because the planar radicals have to distort significantly to form the asymmetric, strained HABI molecule.⁶⁶ Strehmel *et al.*⁶⁷ examined lophyl radical cage escape yields and recombination rates in three ILs of varying viscosities in comparison with dimethylsulfoxide. Cage escape yields were reduced by half in the ILs relative to dimethylsulfoxide, indicating longer cage retention times in the ILs facilitating fast recombination. Remarkably, the radical recombination rate constants for $\text{C}_4\text{mim NTf}_2$, $\text{C}_6\text{mim PF}_6$, and $\text{C}_4\text{mim BF}_4$ were 95 000, 21 000, and 18 000 $\text{M}^{-1}\text{ s}^{-1}$ respectively, whereas the rate constant in dimethylsulfoxide

(20–200 times less viscous) was $5300 \text{ M}^{-1} \text{ s}^{-1}$. It appears that lophyl radical recombination is promoted by the IL environment, possibly through transition state stabilization by means of yet unknown interactions.

Although it is clear that ILs can have significant effects on the reactions and dynamics of solute radicals, there is a much richer chemistry of radicals derived from the ILs themselves. This chemistry is not only determined by the type of anion or cation from which a particular radical is derived but it can also be profoundly influenced by the chemistry of the respective counterion. Ionizing radiation, photochemistry, and electrode reactions can serve as the means of “ionizing the ions.” The thrust of this article is to describe the chemistry of such reactions and the nature and reactivity of radicals thus formed.

2 “IONIZATION OF THE IONS”

In a molecular liquid, ionization (or, more generally, oxidation and reduction of the constituent solvent molecules) produces the so-called *excess electrons* (e^-) and *holes* (h^+), that is, solvent molecules from which the electron has been detached (forming a parent radical cation, which may be stable or unstable) and rapidly relocalized in the bulk solvent. If the solvent molecules have no electron affinity or accessible antibonding orbitals, the excess electron localizes in the voids between the solvent molecules as a “solvated electron”⁶⁸; otherwise the excess electron attaches to a solvent molecule to form a molecular anion. Sometimes, dimer or multimer anions are formed instead, bridging the two extremes of the electron localization: molecular ions and solvated electrons, which can be viewed as clusters of electrons and their solvent cages. Radical cations of nonaromatic molecules tend to deprotonate rapidly, yielding secondary neutral radicals. Sometimes, such “holes” and “electrons” (or their incompletely localized precursors) can migrate faster than molecular diffusion, by a resonance charge-hopping mechanism, and so the charge transfer to the solute is very rapid and efficient, despite the relatively short lifetime of these primary species. This lifetime is, typically, reduced by charge recombination, especially in liquids of low and medium polarity: the Coulomb attraction

between the opposite charges in the geminate pairs (or clusters of such pairs in radiolytic spurs) generated in the ionization or charge separation events pulls the radical ions toward each other. Some reactive species escape, but the majority recombine.

Many of these common intuitions about ionization in organic liquids fail when these liquids are composed of ions. Very generally,^{69,70} the “ionization of ions” produces either radical dications and dianions (if the electron is removed from a cation and accepted by an anion)

or neutral radicals (if the electron is accepted by a cation or removed from an anion)

It is also possible that the electron detached from either of the constituent ions is trapped in anion vacancies and/or interstitials between the cations, similarly to F-centers in irradiated NaCl and other inorganic ionic solids.

Naturally, these doubly charged radicals are inherently unstable, owing to the strong internal Coulomb repulsion, and so such a species rapidly eliminates one of the charges via fragmentation. The typical examples of such fragmentation reactions are deprotonation of radical dications from the aliphatic arms (with the formation of the corresponding alkyl radical in the arm; see Scheme 2)⁷⁰

and halide elimination from the radical dianions of fluorinated anions (reactions 27 and 28 below). These ultrafast fragmentation reactions compete with the equally rapid electron transfer involving the neighboring ion; for example,^{69,70}

The formation of the doubly charged radical ions may seem counterintuitive, as from the energetics standpoint, it appears more likely that the negative charge (“electron”) would be trapped by the constituent cation, whereas a positive charge (“hole”)

would be trapped by the constituent anion. This may indeed be the case in one- or multiphoton ionization and this is certainly the case in electrochemical experiments, but this is not the case in the radiolysis of ILs. Indeed, the typical energies involved in the generation of two to five ion pairs in 5–10 nm spurs through interaction with fast (>0.1 MeV) electrons is 10–20 eV per ionization event, and this energy is more than sufficient to produce superexcited electronic states of the constituent ions, electronically and vibrationally excited neutral radicals, and radical dications and dianions (that otherwise belong to the curiosity cabinets of physical organic chemistry). Furthermore, the excess electron is a highly reducing species that can easily react with certain anions, among them nitrate (*vide infra*).

As both the proton transfer (5) and electron transfer reactions (6) are very rapid and involve the same acceptor (the neighboring anion), the branching ratio of these two reactions largely depends on the stability of the radical dication to deprotonation. Aliphatic cations (such as quaternary ammonium cations) very readily deprotonate from the terminal and penultimate sites of their alkyl arms, because these are the sites of the maximum unpaired electron density in the C^{2+} . Consequently, the yield of the deprotonation is large and $R^+(C^+)$ radicals are the main form of the cation-derived radical in the corresponding ILs.⁷⁰ By contrast, in aromatic cations, the unpaired electron density is mainly on the ring, and the deprotonation from the aliphatic arms is significantly reduced, though it is by no means negligible. Owing to the occurrence of reaction (6), the main form of the “hole” generated in an IL is radical $A^{\bullet}$, irrespective of whether the ionization proceeds from the cation or the anion.

The routine formation of doubly charged radicals makes the radical chemistry of the ILs delightfully exotic, as such species seldom occur in “normal” liquids. However, even the neutralization reaction (4b) results in the unusual situation: the formation of the geminate pair of neutral radicals surrounded by ions (as opposed to the normal situation, which is the geminate pair of radical ions surrounded by neutral molecules).^{69–71} Since there is no direct electrostatic interaction of neutral radicals in an ionic fluid, the radicals may readily escape from such geminate pairs and the chemistry may be dominated by cross-reactions of such escaped radicals as opposed to rapid recombination of geminate radical ion pairs.

At present, little is known about the geminate dynamics of such neutral radicals in ILs, though some classes of ILs have been extensively studied using pulse radiolysis and ultrafast laser spectroscopy.^{72,73} Such geminate pairs are not the general rule, as the neutral radicals that are surrounded by ions can convert to dimeric radical ions by forming two-center three-electron $\sigma^2\sigma^{*1}$ bonds with the parent ions,^{71,73}

restoring “normalcy” (having ionic radical intermediates similar to molecular liquid mechanisms). This is not the only way of such “normalization,” the IL systems exploit several such ways (as discussed in the subsequent sections). The formation of metastable neutral radicals via reaction (4b) is much less frequent than could be expected on the general grounds. Since in the ILs, the (radical) ions are more strongly solvated than neutral radicals, *if a reaction intermediate can be converted to a charged species, then it is typically converted to such a species*. This is one of the most general patterns of radical behavior in the ILs—these liquids “want” to stay ionic!

The hemicolligation reactions mentioned above have precedence in inorganic solids. The ionization of alkali halides, Alk^+X^- , yields an anion-vacancy-trapped electron interacting with six neighboring alkali cations and the $X_2^{\bullet-}$ anion. The latter is formed when the $X^{\bullet}$ atom generated by electron detachment from the parent halide anion forms the $\sigma\sigma^*$ bond with the interstitial X^- . The same reaction also occurs in the ILs composed of Br^- and I^- anions.^{53,57,74,75} Given the high concentration of the parent anions in such neat ILs, reaction (8b) occurs in <100 fs.⁷³ The similar reactions should occur in ILs composed of pseudohalide anions (such as SCN^-), including the popular choice for a chemically inert, hydrophobic anion, the dicyanamide $((NC)_2N^-$, Scheme 1). It was shown⁷¹ that the radical $(NC)_2N^{\bullet}$ derived via reaction (4b) forms the C_2 symmetric $[(NC)_2N-N(CN)_2]^{\bullet-}$ radical anion. For other (pseudohalide) imide anions, which have bulkier substituting groups (such as the NTf_2^- anion, where $Tf = CF_3SO_2$; see Scheme 1), steric hindrance prevents the formation of the dimer anion and neutral Tf_2N radicals are observed instead.⁷⁰ In ILs composed of aliphatic cations (Scheme 1), there

are no accessible antibonding orbitals for the excess electrons to occupy, and the electrons do not attach to such cations. If the ground state anions in such aliphatic IL also have low or negative electron affinity, such electrons can form cavity-trapped “solvated electron” species that are electrostatically bound to several cations forming the cavity.^{48–50,53} It is possible that such cavities originate as anion vacancies.⁷¹ The electron is partially screened from the cation’s positive center by its aliphatic groups, and the optical absorption spectra of such “solvated electrons” resemble those of medium-polarity molecular liquids, suggesting only weak electrostatic interactions with the bulky cations. The reaction and solvation dynamics of such electrons are the subject of active investigation, and we refer the reader to recent reviews.^{52,76,77} Solvated electrons in some ILs may persist for about a microsecond before they decay through geminate recombination with holes or their successor species, including radiolytically generated protons, or they may disappear more quickly by reactions with adventitious scavengers (impurities in the IL). It is also possible that such solvated electrons slowly react with the constituent NR_4^+ cations, with the formation of the corresponding amine NR_3 and the elimination of the terminal $\text{R}^\bullet$ radical, as occurs in water.⁷⁸ The decay of these solvated electrons, either via photoassisted recombination or alkyl arm elimination, can be induced by photoexcitation in the visible region (resulting in <1 ns photobleaching).⁷⁹

In ILs composed of aromatic cations, the π -systems of the cations can readily accommodate the negative charge, and so electrons are promptly trapped therein. It is possible that excess electrons exist fleetingly in aromatic cation ILs, and there is some support to this conjecture both from the experiment^{72,73} and theory^{80,81}. However, such excess electrons would be inherently unstable with respect to attachment after the solvation dynamics have come to equilibrium. The typical examples of such electron-accepting cations (C^+) are “aromatic” cations shown in Scheme 1; neutralization of these cations results in the formation of trigonally distorted 2-imidazolyl (Scheme 2) and planar 4-pyridinyl radicals ($\text{C}^\bullet$). The latter radicals and 2-alkyl-substituted imidazolyl radicals are unreactive toward their parent cations, whereas in some ILs, the 2-imidazolyl radicals attack the parent cation at the 2-position (reaction 8b) to form a $\text{C}(2)\text{--C}(2)$ $\sigma\sigma^*$ bound C_2 symmetrical “gauche”

dimer radical cation $\text{C}_2^{+\bullet}$, which exhibits a low energy $\sigma\leftarrow\sigma^*$ absorption band.⁷¹ Since this $\sigma\sigma^*$ bond is rather weak, reaction (8b) is reversible and the dimerization is favorable in some ILs but not in others. If the anions are compact, strong solvation interactions with the parent cation shift the equilibrium to the left side of reaction (8b); if the interactions are weaker (which is the case for bulky and extended anions that also tend to cluster, such as NTf_2^-), the equilibrium is shifted right to the dimer radical cation. The resulting $\text{C}_2^{+\bullet}$ cation radicals formed in reaction (8b) resemble the A_2^{--} anion radicals formed in reaction (8b). A peculiarity of such “double dimerization” is that the recombination can occur in the following two ways:

In halide ILs, the signature of this branched dimerization is a very rapid (geminate) generation of X_3^- (from $\text{X}^- + \text{X}_2$). If reaction (9b) does not occur, the only chemical pathway to X_3^- is via the disproportionation of the escaped X_2^{--} radicals, which is slow. Time-resolved Br K-edge X-ray absorption studies on C_6mim Br photoexcited by a 200-nm laser suggest rapid (<1 ns) formation of a closed-shell species with the Br–Br bond, consistent with the occurrence of reaction (9b).⁶²

How extensive is the fragmentation of the constituent ions in the “ionization of the ions?” The overall degradation of NTf_2^- in irradiated C_4mim NTf_2 was estimated as 2.2 species per 100 eV absorbed energy.⁸² Given that the typical ionization yield in an organic liquid is three to five ion pairs per 100 eV, it is seen that the “ionization of the ions” generally results in their fragmentation (which competes with the recombination). We proceed to look more closely at the radicals derived from the constituent ions.

3 NONAROMATIC ANIONS

Although the formation of Br_2^{--} and I_2^{--} in aliphatic and aromatic ILs is well established,^{53,74,75,83} no such species were apparent for chloride ILs.⁸⁴ This suggests that reaction

(8b) competes with hydrogen abstraction from the organic cation:

The energies of the H–X bond change from 5.9 to 4.5 to 3.8 eV from F to Cl to Br, hence reaction (10) can outcompete reaction (8b) for chlorine but not bromine, and $Cl_2^{\cdot-}$ is not formed. Consequently, no chloride-derived radicals can be traced to the anion, as $R^{\cdot}(C^{+})$ can also be generated via reactions (5) and by $H^{\cdot}$ atom abstraction reaction

Similarly, no distinctive anion-derived radicals are observed in ILs composed of BF_4^{-} and PF_6^{-} . For PF_6^{-} and BF_4^{-} , mass spectrometry analyses indicate the occurrence of $F^{\cdot}$ atom substitution/addition products,^{82,85}

whereas EPR spectra indicate no anion-related radicals. Since the irradiation of KPF_6 and KBF_4 yields various P- and B-centered radicals, the absence of such anion-derived radicals in the ILs suggests that $F^{\cdot}$ atoms promptly abstract hydrogen via reaction (10). When tetracyanoborate anion, $B(CN)_4^{-}$, replaces the BF_4^{-} anion, two B-centered radicals are observed that are formed via reactions

In the gas phase, BF_3 has near-zero or negative electron affinity versus 3.4 eV for $B(CN)_3$ and 3.94 eV for C_1mim^{+} .⁸⁴ Had the $BF_3^{\cdot-}$ radical been formed via reaction (13), it would promptly donate the electron to any acceptor including the constituent cation. Equally, significant is nonobservation of the $\cdot BF_2$ radical. The dissociation energy for F_2 (1.61 eV) is considerably lower than this energy for C_2N_2 (5.78 eV). Consequently, the $BX_3 + X^{\cdot}$ pathway is preferred to the $\cdot BX_2 + X_2$ pathway by almost 5.7 eV for $X = F$, whereas the second pathway is preferred by 0.7 eV for $X = CN$. Therefore,

while reaction (12) occurs for the tetrafluoroborate anions, reaction (14) is preferred for the tetracyanoborate anions. Turning to more complex inorganic anions, a very important example is hydrogen sulfate, which can be used to generate $H^{\cdot}$ atoms:

The $H^{\cdot}$ atoms abstract hydrogen from the alkyl arms of the cations (reaction 11), but for aromatic cations, the main reaction is H-atom addition

For imidazolium cations, this addition is in the C(2) position, yielding $Q_2H_2^{+*}$; for pyridinium cations, it is in the C(4) position. The same radical cation adduct CH^{+*} can be formed via the reversible protonation of $C^{\cdot}$ radical by acids:

and both pathways (16) and (17) to this radical cation have been observed experimentally.^{84,86} Such proton adducts are remarkably stable (some of these species persist to 350 K) and probably decay via the reaction

The $H^{\cdot}$ atom formation does not necessarily involve reaction (15); the electron can be scavenged by any protic impurity in the IL, including the one that is photo- or radiolytically generated (such as $H^{\delta+}A^{\delta-}$ and H_3O^{+}). Another likely source of the $H^{\cdot}$ atoms is the homolysis of the C–H bonds in the electronically excited states of the cations that are generated either by charge recombination or direct excitation (e.g., during radiolysis),

Another inorganic anion of practical interest is nitrate, as nuclear separations based on ILs typically involve 1–5 M nitric acid solutions in contact with the IL, and the nitrate anion is extracted from such aqueous solutions.⁸⁷ Radiolysis of $C_4mim NO_3$ results in the accumulation of $NO_2^{\cdot-}$ anions.⁴⁷ In the EPR spectra obtained from irradiated $C_2mim BF_4/C_2mim NO_3$, the strongest resonance lines are from the $NO_2^{\cdot}$ and NO_3^{2-*} radicals.⁸⁴ In KNO_3

(serving as a reference system), there is also the $\text{NO}_3^\bullet$ radical that is lacking in the ILs. In both aliphatic and aromatic IL nitrates, the radicals derived from the organic cation (such as $\text{C}^\bullet$) are missing. In aqueous solutions, the $\text{NO}_2^\bullet$ radicals form not only via the prompt homolysis of the excited $\text{NO}_3^{2-\bullet}$ anion but also via a slower reaction of $\text{NO}_3^{2-\bullet}$ (or HNO_3^{--}) with acids, $\text{H}^{\delta+}\text{B}^{\delta-}$ (including water), yielding the corresponding oxide anion as a by-product:

The $\text{NO}_3^{2-\bullet}$ radical is readily protonated by weak acids, and it is likely that the $\text{NO}_2^\bullet$ radicals observed in the ILs are generated in these secondary reactions. The $\text{NO}_2^\bullet$ radical can also be produced in reactions of $\text{H}^\bullet$ atoms and NO_3^- :

When tetrabutylammonium nitrate is irradiated at 77 K and then warmed to 225 K, the $\text{NO}_3^{2-\bullet}$ and $\text{NO}_2^\bullet$ radicals decay, and the signal of the $\text{NO}_2^{2-\bullet}$ (or HNO_2^{--}) radical appears. The formation of this radical could be due to electron transfer from $\text{NO}_3^{2-\bullet}$ to NO_2^- ; the nitrite (found among the stable radiolytic products) might be formed via the dissociation of the excited state NO_3^- anion. In $\text{C}_2\text{mim NO}_3/\text{BF}_4$, this $\text{NO}_2^{2-\bullet}$ radical is not observed; instead, at 175–180 K, the $\text{NO}_3^\bullet$ radical is observed. The observed low yield of the $\text{NO}_3^\bullet$ radicals in the irradiated ILs as compared to inorganic nitrates can be accounted for by high reactivity of this radical, by H abstraction or electron transfer.

A large subset of the simple anions that are used in IL synthesis can be represented as RB^- , where R- is an alkyl or alkoxy group (or their perfluorinated analogs) and -B is an inorganic base (such as $-\text{SO}_3^-$, $-\text{CO}_2^-$, and $-\text{PO}_2^{2-}$). One-electron oxidative fragmentation of several such anions is well known (e.g., Kolbe reaction for the carboxylates),^{84,88} and these better-known reactions exemplify a more general pattern of the loss of base upon neutralization

Table 1 Radical products derived from the constituent anions and identified in the frozen ILs using EPR spectroscopy (the deprotonated forms of the radicals are given).⁸⁴

Anion	Radicals observed
X^{-a}	$\text{X}_2^{-\bullet}$

which yields the corresponding fragment radical $\text{R}^\bullet$ (Table 1). Reaction (23) occurs in most of the ILs composed of RB^- anions, even if the ground state of the intermediate radical $\text{RB}^\bullet$ is relatively stable. This is explained by the fact that reaction (23a) is strongly exergonic and the neutral radical $\text{RB}^\bullet$ is generated in an electronically and/or vibrationally excited state. The potential presence of water increases the likelihood of reaction (23b) involving the relaxed $\text{RB}^\bullet$ radical through the hydration of residue B with the formation of acids

Reaction (24) causes a radiation-induced increase in proticity.⁸⁹ The fluorination of the RB^- anions (which is a popular approach to increasing the hydrophobicity and chemical durability of ILs) has little effect on the facileness of reactions (23). For alkyl and alkoxy RB^- anions, intra- or intermolecular deprotonation from the aliphatic moiety competes with reaction (23b), for example,

and the latter radical (in deprotonated form) can also be produced via secondary reactions

Reactions (25) and (26) can be readily generalized to include other RB[−] anions. Table 1 summarizes the radicals observed using EPR spectroscopy.⁸⁴ The product analyses are consistent with these observations: it is precisely because of the occurrence of reaction (23) that most of the commonly used constituent anions undergo appreciable fragmentation upon radiolysis. The stabilization of the anion could be achieved either via (i) preventing reaction (23a) through increasing adiabatic electron detachment energies (EDEs) of the constituent anions (Table 2) or (ii) stabilization of the intermediate radical. Increasing the EDE of the anion has little actual effect on its *radiation* stability, as the ionization events in radiolysis are energetic (5–20 eV) and reaction (23a) still occurs.

The simplest of the RB[−] anions is acetate. In radiolysis of C₂mim and C₄mim CH₃CO₂[−], the EPR spectrum recorded at 50 K exhibits the resonance lines of the methyl radical superimposed on the

broad lines from Q₂H[•] and R[•](C⁺) radicals; there is no evidence of reaction (25b). The high yield of the R[•](C⁺) radical suggests that the methyl radicals can abstract hydrogen from the aliphatic arms of the cation. At 175 K, thermally activated methyl radicals add to Q₂H⁺. When the sample irradiated at 77 K is stored at this temperature, the methyl radical fully decays, and the EPR spectrum reveals the presence of the [•]CH₂CO₂[−] (or the [•]CH₂CO₂H) generated via reaction (26). Thus, the methyl radical released in reaction (23) decay (i) by H abstraction from both of the constituting ions and (ii) by thermally activated addition to the imidazolium cation.

When a trifluoromethyl group replaces the methyl group in acetate, the main feature is a signal from [•]CF₂CO₂[−] radical; there is also a weaker signal from the [•]CF₃ radical. The likely origin of this [•]CF₂CO₂[−] radical is dissociative electron attachment (DEA) to the parent anion proceeding via the radical dianion intermediate:

The radiation stability of anions with long fluorinated aliphatic chains (used in some applications where greater IL hydrophobicity is required) is poor. In tetraalkyl ammonium and phosphonium pentafluoroacetate, high yields of CF₃[•]CFCO₂[−] and [•]CF₂CF₂CO₂[−] radicals were observed, while there was no evidence for reaction (23) occurring. The propensity to generate fluoride limits the viability of such anions for applications in high radiation fields. As observed above, aliphatic carboxylates have similar limitations owing to the ease of reaction (23b). Examination of the longer chain homologs of the carboxylates, sulfates, and diphosphates indicates that *the longer was the aliphatic chain in the RB[−] anion, the more extensive was the fragmentation by deprotonation (such as reaction 25b) as compared to reaction (23b).*⁸⁴

Another representative class of the RB[−] anion is sulfonates. The resonance lines from [•]CH₂SO₃[−], CH₃SO₃[•], and [•]CH₃ are discernible in EPR spectra of irradiated frozen ILs consisting of the methanesulfonate anions. Above, we have compared aliphatic carboxylates and their perfluorinated analogs; the same comparison can be made for the alkylsulfates and alkylsulfonates. One of these fluorinated anions, triflate (TfO[−]), is a popular anion choice for IL synthesis. Radiolysis of C_Nmim CF₃SO₃[−] yields [•]CF₃ and [•]CF₂SO₃[−]

(or its protonated form). Unlike the case of C_N mim $CF_3CO_2^-$, where the $\cdot CF_2CO_2^-$ radical accounts for most of the radicals observed, the yield of these two radicals in the TfO ILs is low (<5% total radical yield). No evidence for the $CF_3SO_3\cdot$ radical (analogous to the $CH_3OSO_3\cdot$ and $CH_3SO_3\cdot$ radicals observed in the reference alkylated anion systems) was found in these ILs, suggesting that this $CF_3SO_3\cdot$ radical is unstable. The estimates for the C–S bond dissociation energies given in Table 2 indicate that the gas-phase C–S dissociation barrier for $CH_3SO_3\cdot$ radical is considerably greater as compared to the $CF_3SO_3\cdot$ radical (1.04 vs 0.3 eV), which may account for the instability of the latter species. Extending the perfluorinated alkyl chain greatly increases the yield of reaction (27) for such anions, as the longer chain provides more sites for fluoride loss and increasing chain length decreases the effect of the negatively charged SO_3^- group (repelling the excess negative charge), resulting in more efficient electron trapping.

A closely related anion to TfO^- is bistriflimide, NTf_2^- , which is widely utilized in IL synthesis owing to its high hydrophobicity.⁹⁰ The three anion-derived radicals observed in the bistriflimide ILs are $\cdot NTf_2$, $\cdot CF_2SO_2NTf^-$, and $\cdot CF_3$ (which accounts for 2–5% of the total radical yield). Therefore, in addition to reaction (4b), bistriflimide might undergo DEA typical of other fluorinated anions, albeit with a small yield, as well as N–S fragmentation.^{55,58}

Mass spectrometry data suggest the occurrence of both N–S and S–C scission in this anion, as there are stable products, such as $(CF_3)_2SO_2$, imidazolium cations 2-substituted by $CF_3SO_2^-$ and $TfNH$ -groups,^{82,85} and $TfNH$ adducts of tetraalkylammonium cations,⁹¹ all of which can be explained only through the occurrence of this scission. According to Table 2, the S–C dissociation energy for the $CF_3SO_2\cdot$ and $CF_3SO_3\cdot$ radical are comparable, and both are chemically unstable, undergoing reaction (23b) that accounts for the radiolytic generation of sulfite.⁸⁹ The fragmentation of NTf_2^- is likely to involve electronically excited anion⁸⁴:

4 AROMATIC ANIONS

Given the propensity for RB^- anions to fragment on neutralization, is it possible to stabilize the intermediate radical $A^\cdot$ by π -conjugation? Theoretical calculations^{84,88} indicate that reaction (23a) is least exothermic for monocarboxylated benzenes, such as benzoic (**1** in Scheme 3) and (thio)salicylic acids (**2** and **3**).

Irradiated tetraalkylphosphonium benzoate yields radical **1a** (Scheme 3) that accounts for ~20% of the total radical yield, as determined by EPR spectroscopy.⁸⁴ There is also a weak EPR signal from radical **1b**, but no radical **1c** (generated via reaction 23) is observed. In crystalline tetrabutylammonium benzoate, the lines of radical **1c** are superimposed on the resonance line of radical **1a**. When the same material is quenched from a melt at 77 K, there are resonance lines of radical **1d**. It appears that benzoate serves not only as a hole scavenger (yielding radical **1a**) but also as an electron and H-atom acceptor (yielding radicals **1d** and **1b**, respectively). Neither one of these reaction pathways results in the fragmentation of the anion. In the salicylate IL, there are lines from radicals **2a** and **2b**, with radical **2b** accounting for ~40% of the total radical yield. The phenoxyl radical **2a** decays at 200 K, whereas radical **2b** persists to 220 K; at intermediate temperatures, the narrow line of radical **2b** is superimposed on the weaker lines from radical **2c**. By contrast, the EPR spectrum of irradiated methyltriocetylammmonium salicylate was dominated by radical **2a**, whereas radical **2b** was not observed; instead there were overlapping lines from radicals **2a**, **2c**, and **2d**; the latter radical is the product of reaction (23b). As radical **2a** has an EPR spectrum similar to that of radical **2e**, it is possible that the latter EPR signal originates from electron rather than hole reactions. Similar radical products were also observed for the thiosalicylate. Given these results, one might expect that sulfonated benzenes may also be resistant to fragmentation; however, radicals **4a** and **4c** were

Scheme 3 Fragmentation patterns of complex aromatic anions.

found in irradiated tosylate ILs, indicating the occurrence of reactions (23b) and (25b), and the $\text{H}^\bullet$ adduct **4d** was also observed; such $\text{H}^\bullet$ atom additions also occurred in other ILs composed of aromatic anions.

As both the dicyanamide and bistriflimide yield few radical fragments in radiolysis of the corresponding ILs, we conjectured that combining the $>\text{N}^-$ group with an aromatic π -system may yield hydrophobic anions that are particularly resistant to radiolysis. Phthalimide (**5**) is the simplest such anion. Irradiation of sodium phthalimide produced the protonated form $\text{HA}^{\bullet-}$ (radical **5a**) of the dianion (formed via reaction 4a) and radicals **5c** and **5b** (the latter is formed by ring-opening in the oxidized phthalimide). The EPR spectra for phthalimide ILs exhibit the narrow line of radical **5a** that

accounts for 20–35% the total radical yield. Above 150 K, there are also weak lines due to radical **5c**. In these ILs, there is no evidence for the occurrence of radical **5b**. Thus, the phthalimide provides another example of a radiation-resistant anion.

To sum up this exposition on anion chemistry, the extent of anion fragmentation greatly varies between ILs. The least stable anions are aliphatic carboxylates, aryl- and alkyl- sulfonates, alkylsulfates, and dialkylphosphates—as well as their fluorinated derivatives. Among the fluorinated sulfonates, only the smallest anion, TfO^- , is relatively stable; longer chain anions are readily defluorinated. The fragmentation also occurs for small inorganic anions, such as nitrate and tetracyanoborate. Nevertheless, there are exceptions to this general rule.

The first exceptional class of anions is the benzoate and its oxo- and thiooxo- derivatives, and the second exceptional class consists of imides (there could be more such classes). The apparent reason for the imide stability is that these anions do not belong to the RB^- class, so their radicals *cannot* undergo reaction (23b). The corresponding N-centered radicals appear to be unreactive toward the constituent cations and so decay by back recombination. For dicyanamide, this N-centered radical undergoes additional stabilization via reaction (8b). While oxidative fragmentation is suppressed for these imides, the phthalimide and succinimide readily trap the electrons and react with $H^\cdot$ atoms.

5 CATION CHEMISTRY

For aliphatic cations, the redox chemistry is simple: the ionization of such cations results in the formation of H-loss $R'(C^+)$ radicals (multiple examples of this kind are given elsewhere).⁷⁰ However, aromatic cations exhibit more complex and interesting radical chemistry. We have already considered several types of reactions involving imidazolium cations (summarized in Scheme 2). In particular, we observed that Q_2H^+ cations can react with the electrons giving either $Q_2H^\cdot$ radicals and/or $(Q_2H)_2^{+\cdot}$ dimer radical cations. The $Q_2H^\cdot$ radicals are readily protonated to yield $Q_2H_2^{+\cdot}$ cations, whereas $(Q_2H)_2^{+\cdot}$ and $Q_2R^\cdot$ radicals (derived from Q_2R^+ cations) are not protonated. The eventual fate of the $(Q_2H)_2^{+\cdot}$ is presently unclear; we have suggested that this radical cation decays by recombination (reaction 9) or proton transfer reaction (32),

yielding the Q_2 -substituted 2-imidazolyl radical.^{62,86} This radical could be the intermediate in the oligomerization of the imidazolium cations (under mildly reductive conditions) leading to deterioration of IL properties. The $Q_2(Q_2H)^\cdot$ radical can recombine with $A^\cdot$ (or $A_2^{\cdot-}$), yielding the asymmetric dimer cation $Q_2(Q_2H)^+$ (which can also be generated via reaction (2a)),

and two such $Q_2(Q_2H)^\cdot$ radicals can either combine to form a tetramer or they can disproportionate to yield $(Q_2)_2$ (which can also be generated via reactions 1 and 2)

Thus, the same products can be generated via the radical and carbene chemistry.⁶² Theoretical considerations also suggest that the $Q_2(Q_2H)^\cdot$ radical can react with the parent cation,

to yield trimer radical cation $Q_2(Q_2H)_2^{+\cdot}$, which, in turn, can recombine yielding the $Q_2(Q_2H)^+$ or neutral trimer $Q_2(Q_2H)_2$. The C(2)–C(2) conjugation cannot extend over the tetramer, owing to steric hindrance in the resulting oligomers.⁶²

Nuclear magnetic resonance (NMR) provides the most direct structural information on the products formed in the ILs.^{56,62} The calculated proton chemical shifts ($\delta(^1H)$) for the ring protons in C_1mim^+ are ~ 8 ppm for (hereafter, all chemical shifts are given vs tetramethylsilane). In the corresponding $(Q_2H)_2$ dimer, owing to the loss of the aromaticity, the H(2) and H(4,5) protons exhibit $\delta(^1H)$ 4.2 and 5.8–6 ppm, respectively. 1H NMR spectroscopy⁵⁶ of electrochemically degraded $C_4mim BF_4$ does reveal a new set of protons with $\delta(^1H) \approx 5.7$ ppm that are the signature of the neutral oligomers. The estimated carbon-13 chemical shifts for C(4,5) in the $(Q_2H)^+$ and $(Q_2H)_2$ are similar (120 vs 115 ppm), whereas for C(2), the chemical shift changes from 127 to 91 ppm. In ^{13}C NMR spectra taken before the electrolysis of $C_4mim BF_4$, there are lines by C(2) and C(4,5) of the parent cation with $\delta(^{13}C) \sim 134$ and 120 ppm, respectively. After the electrolysis, these two peaks disappear, whereas three new peaks in the 80–95 ppm region appear in the cathodic liquid. These resonance lines are clearly from the *reduced* carbon-2 in (several) neutral oligomers.

While such C(2)–C(2) bonding reactions are prominent in the cathodic fluid, it is not yet clear that the oligomerization of this type is important in radiolytic and photolytic decomposition of the ILs.⁸⁶ The dimer species were observed in the mass spectra of irradiated imidazolium ILs,

along with several other products that can be considered as the products of cross recombination of various radicals discussed in this article.⁸² The radiolytic yields for decomposition of the cations were ~ 2.8 per 100 eV for C₄mim NTf₂ and ~ 3.7 per 100 eV for C₄mim TfO, respectively.⁸² During this decomposition, ~ 0.26 molecules of H₂ per 100 eV⁹² were generated, indicating considerable loss of hydrogens, primarily from the alkyl arms of the substituted imidazolium cations.

Owing to the formation of radiolytic products, the viscosity of the irradiated IL samples increases considerably.^{47,86} The NMR spectra of C₄mim TfO and C₅mim NTf₂ exposed to 6–8 MGy indicate $\sim 30\%$ loss of α - and β -hydrogens from their long arms. Concomitant with these changes is the appearance of new lines in the ¹³C NMR spectra, at ~ 1 – 10% of the cation concentration. Cross recombination of R'(C⁺) radicals and polymerization of olefinic products of their disproportionation would yield products exhibiting such ¹H and ¹³C NMR spectra. Bridging through the alkyl arms is also suggested by mass spectrometry: there is a diffuse continuum of mass peaks centered at $m/z 670 \pm 300$, stretching out to $m/z 1700$, and accounting for 95% of the total ion count. The yield of the polymer in C₄mim TfO was ~ 0.23 monomer units per 100 eV, which is comparable to the H₂ yield. This behavior is clearly different from electrochemical reduction, where the oligomerization is driven by the C(2)–C(2) condensation. This difference is readily accounted for by the more energetic nature of radiolysis, in which the R'(C⁺) radicals can be formed.

Apart from the reactions that are induced by radiolytic or electrochemical reduction of the imidazolium cations, free radicals derived from the cations can be generated via secondary radical reactions and reactions with the products of carbene chemistry (Section 1). In the case of 2-alkyl-substituted imidazolium cations Q₂R⁺, steric hindrance inhibits C(2)-addition reactions, and abstraction takes place, for example:

Such reactions do not exhaust the richness of radical chemistry of imidazolium cations. Excitation of the cation may involve N–C cleavage in the excited state of the cation

with the formation of an 1-ene (such reactions were observed in the gas phase)⁸⁶ or homolytic dissociation

A similar reaction may also occur in the ground or excited states of the 2-imidazolyl radical:

Reaction (38) is a C–N bond scission reaction (39) concerted with H transfer from the leaving group. Irradiation of 1,3-di(*tert*-butyl)imidazolium tetrafluoroborate produces two radicals: Q₂H[•] and Q₃CHMe₂[•]. The latter radical is also observed in radiolysis of 1,3-di(*iso*-propyl)imidazolium tetrafluoroborate. When the irradiated sample of 1,3-di(*tert*-butyl)imidazolium tetrafluoroborate is warmed above 125 K, the [•]CMe₃ gradually appears (together with a much weaker signal from Q₂H₂⁺⁺), whereas the signal from Q₂H[•] gradually disappears. This behavior provides evidence for reaction (40). In the gas phase, collisionally activated imidazolium cations lose their aliphatic arms through reaction (38). Reaction (38) requires less activation than reaction (39). For example, for C₂mim⁺, the corresponding energy barriers are 1.17 and 4.4 eV.⁸⁶ For reaction (40), the dissociation energy of the N–CH₃ bond is only 77 meV, even for 1,3-dimethyl-2-imidazolyl, that is, the Q₃R[•] radicals are thermodynamically unstable. The alkyl substitution at C_α further reduces this energy, facilitating reaction (40). Further weakening of the N–R bond can be achieved by replacing the alkyl arm with the alkoxy arm. For 1,3-dimethoxy-2-imidazolyl, reaction (40) is *exergonic* by 1.06 eV, whereas reactions (38) and (39) are endergonic by 1.29 and 2.36 eV, respectively. These estimates suggest the ease of losing the N-methoxy arms. Irradiation of 1,3-dimethoxy-imidazolium hexafluorophosphate and 2-methyl-1,3-dimethoxy-imidazolium bistriflimide yields the formyl and hydroxymethyl radicals. The latter is generated via rearrangement of the leaving MeO[•] radical that can be formed either via reaction (39) or (40). The formation of the formyl radical and the absence of the Q₃⁺ (OCH₂[•]) radical (generated in reaction 5) can be accounted for by energetics: our calculations indicate that the Q₃⁺ (OCH₂[•]) radical would be

unstable,

decaying to yield the formyl radical.⁸⁶

6 CONCLUDING REMARKS

With so many reactive intermediates generated in the “ionization of the ions,” it is inevitable that these react with many solutes in the ILs generating a great variety of secondary radicals. Many of such reactions are common reactions of electrons, holes, and small radicals ($\text{H}\cdot$, $\text{Me}\cdot$) that also occur in many solvents. However, there are also important differences. Because the EDE of the constituent anions tends to be low and the electron affinity of the constituent aromatic cations is relatively high, in such aromatic ILs, electron (and energy) transfer reactions involving these primary species with many solutes are disfavored. A spectacular example of this behavior concerns the trialkylphosphates, $(\text{RO})_3\text{PO}$.⁷⁰ Tributylphosphate (TBP) is the common solvent modifier and the extracting agent in spent nuclear fuel processing. For example, in PUREX (Plutonium-URanium EXtraction) process, 30 wt% TBP in dodecane is used to extract U(VI) and Pu(IV) from the nitric acid raffinate.⁹³ In irradiated alkane solvents, the excess electron rapidly reacts with the TBP, yielding $\text{R}\cdot + (\text{RO})_2\text{PO}_2^-$. This DEA reaction leads to the formation of dibutylphosphates that extract trivalent lanthanide radionuclides into the organic phase, undermining separations selectivity. However, even when 10–40 wt% of trimethylphosphate is added to imidazolium IL, the prompt yield of methyl radicals is low, suggesting that most of the “electrons” react with the constituent cations rather than the solute.⁷⁰ High radiation resistance of another class of common extracting agents, crown ethers, in the ILs has also been demonstrated.⁹⁴ It appears that aromatic IL solvents may exert significant radioprotective effect on many of the solutes and cosolvents used in such nuclear separations.

We hope that this article will stimulate more interest in free radical chemistry, radiation chemistry, photochemistry, and electrochemistry of the new “salt of the Earth”—IL.

Radical Cation/Anion and Neutral Radicals: A Comparison

Amber N. Hancock and J. M. Tanko

Department of Chemistry, Virginia Polytechnic Institute and State University, Blacksburg, VA, USA

1 INTRODUCTION: RADICAL CATION/ANION AND NEUTRAL RADICALS: A COMPARISON

Over the past several decades, radicals and radical ions have emerged as an important class of reactive species. Recognition of their role as potential intermediates in numerous organic and bio-organic reactions and development of several new synthetic methods based on their chemistry has attracted significant attention. This article explores parallels between radical and the equivalent radical ion reactions; in cases where available data facilitates comparison. Generally, it is shown that the results of one class extrapolate to the other in a useful way. However, as is seen, the investigator should exercise extreme caution when inferring reactivity trends for a radical ion from a radical. A seemingly subtle molecular change such as introduction of charge can have a profound impact on structure, stability, and reactivity of a molecule.

2 CYCLOPROPANE RADICAL CATIONS AND ANIONS

2.1 Cyclopropylcarbinyl $\rightarrow$ Homoallyl Rearrangements

2.1.1 Radical Ion Probes/Clocks Based on the Cyclopropylcarbinyl $\rightarrow$ Homoallyl Rearrangement

Unimolecular rearrangements based on cyclopropane chemistry are useful from a mechanistic

perspective (i.e., as mechanistic probes or radical ion clocks) (see **Radical Kinetics and Clocks**). The mechanistic probe approach is essentially an intramolecular trapping experiment. A structural feature (e.g., a cyclopropyl group) is incorporated into the substrate that, in principle, will lead to a rearrangement uniquely ascribed to a radical or radical ion intermediate. Historically, the use of a cyclopropyl group in such an experiment is predicated on the expectation that the relief of ring strain will drive the rearrangement. The prototypical example of such a process, the cyclopropylcarbinyl $\rightarrow$ homoallyl neutral radical rearrangement (1) is fast ($k \approx 10^8 \text{ s}^{-1}$) and essentially irreversible.¹

The mechanistic probe approach is founded on two critical assumptions: (i) structurally rearranged products arise exclusively from the single-electron transfer (SET) pathway and (ii) the rearrangement is rapid and (preferably) irreversible. Although the kinetics (and mechanism) of unimolecular rearrangements of neutral radicals have been extensively studied, until recently, very little was actually known regarding analogous rearrangement of radical ions. Frequently, it was (and is still) assumed that structural features that lead to facile rearrangement of neutral free radicals would do the same for radical ions.

2.1.2 Cyclopropylcarbinyl $\rightarrow$ Homoallyl-Type Rearrangements of Radical Anions Generated from Aromatic Ketones

In 1990, we reported our first results pertaining to the chemistry of radical anions generated from substituted phenyl cyclopropyl ketones (Scheme 1).² For R = alkyl or hydrogen, ring opening of $1^{\bullet-}$ was found to be very slow, and reversible with an equilibrium constant favoring the ring-closed radical anion ($k_o < 10 \text{ s}^{-1}$ and $K_{eq} = k_o/k_{-o} = 10^{-8}$ for R = H).^{2,3} These results suggested that there were two important considerations in the design of radical ion probes based on the cyclopropylcarbinyl $\rightarrow$ homoallyl rearrangement: (i) ring strain (the relief of which favors ring opening) and (ii) resonance energy (which may help or hinder rearrangement, depending on the specific system). Thus for $1^{\bullet-}$ (R = H or alkyl), ring opening is disfavored (kinetically and thermodynamically) because there is a loss of resonance energy associated with ring opening (the ring-closed radical anion is highly delocalized). Placement of radical-stabilizing substituents (R = phenyl or vinyl) on the cyclopropyl group partially compensates for this loss of resonance energy, and ring opening becomes more favorable ($k_o \approx 10^6\text{--}10^7 \text{ s}^{-1}$ for R = CH=CH₂ or Ph).⁴

On the basis of this reasoning, spirocyclohexadienones **3** emerged as particularly attractive substrates because ring opening of the corresponding radical ions would be driven by both the relief of cyclopropane ring strain and an increase in resonance energy, because of the formation of

an aromatic ring. Both the direct and indirect (mediated) electrochemistry of **3a-c** were characterized by rate limiting electron transfer (suggesting a rate constant for ring opening $\geq 10^7 \text{ s}^{-1}$ for their corresponding radical anions). From the indirect electrochemistry, rate constants for electron transfer between **3a-c** and a series of aromatic radical anions were measured, and from these results, reduction potentials and reorganization energies were derived using Marcus theory. The value of the symmetry coefficient (α , derived from the direct electrochemistry) and reorganization energy (λ , derived from the Marcus treatment) are consistent with a radical anion which has a discrete lifetime (i.e., electron transfer and ring opening are not concerted).⁵

For the unsymmetrical radical anions, ring opening (Scheme 2) occurs with modest selectivity favoring formation of the more substituted (stable) radical anion (in a 10:1 ratio for $3c^{\bullet-}$ and a 1.2:1 ratio for $3b^{\bullet-}$).⁵ The observed regiochemistry for ring opening is very similar to that observed for the 2,2-dimethylcyclopropylcarbinyl and 1-methylcyclopropylcarbinyl neutral free radicals (where the ratios are 6.7:1 and 1.2:1, respectively).^{1a} These neutral radicals rearrange with rate constants $>10^8 \text{ s}^{-1}$, and it appears likely that rate constants for ring opening of radical anions $3b^{\bullet-}$ and $3c^{\bullet-}$ are of the same order of magnitude. Radical anion $4^{\bullet-}$ ((2)⁶ reproduced by permission of the American Chemical Society) was studied by direct electrochemical techniques. Because of extended conjugation in the ring-closed form (compared to spirocyclohexadienones **3**⁻), the rate constant for

Scheme 1 Phenyl cyclopropyl ketones radical anion ring opening. [Reprinted with permission from Ref. 2. Copyright 1990 American Chemical Society.]

Scheme 2 Unsymmetrical radical anions ring opening.

ring opening of $4^{\bullet-}$ is sufficiently slow that it can be measured directly by cyclic voltammetry (CV). In dimethylformamide (DMF), $k_o = 140 \text{ s}^{-1}$.⁶

[Reprinted with permission from Ref. 6. Copyright 2005 American Chemical Society.]

Because of the regiochemistry of radical anion ring opening, spirocyclohexadienone **3c** emerged as a particularly attractive probe for SET because it allows clear experimental distinction between products formed via SET as opposed to a polar pathway (Scheme 3). Ring opening via a polar pathway (essentially an S_N2 reaction) would result in product(s) where the nucleophile was attached to the least-substituted carbon of the cyclopropyl group **6**; an SET process would yield a product where the nucleophile was attached to the more substituted carbon **5**. In this manner, it was shown that Grignard ($RMgX$) and alkyllithium reagents (RLi) react with **3c** mainly via an SET pathway.

The results pertaining to the mechanism for reaction of **3c** with dialkyl lithium cuprates (R_2CuLi) were ambiguous, and could be accounted for by either an SET or a polar pathway. However, one limitation associated with the use of **3c** was discovered.⁷ In protic solvents (PhS^- as nucleophile) reaction of **3c** was found to involve a rare $S_N2(C+)$ mechanism.⁸

2.1.3 Cyclopropylcarbinyll $\rightarrow$ Homoallyl-Type Rearrangements of Radical Anions Generated from Aliphatic Ketones

Radical anions derived from **7a** and **7b** undergo cyclopropane ring opening, slightly favoring the 3° distonic radical anion in the case of **7b^{•-}** (Scheme 4). Electron transfer was found to be the rate limiting step regardless of whether the reduction was carried out directly (CV) or indirectly (homogeneous redox catalysis) suggesting a rate constant for ring opening $\geq 10^7 \text{ s}^{-1}$. (The value of α derived from the direct electrochemistry suggested these radical ions do have a discrete lifetime).⁹

Because the kinetics of both the direct and mediated reduction of **7a** and **7b** involves rate limiting electron transfer, the rate constant for ring opening could not be determined. However, it was reasoned that the corresponding cyclobutyl derivative would undergo ring opening at a significantly lower rate,

Scheme 3 Cyclopropane ring opening via the polar pathway.

Scheme 4 Ketyl radical anions ring opening. [Reprinted with permission from Ref. 9. Copyright 2002 American Chemical Society.]

and that ring opening might be the rate limiting step for this system. In fact, the rate constant for ring opening ((3) Reprinted with permission from Ref. 6. Copyright 2005 American Chemical Society.) of $8^{\bullet-}$ ($k = 8 \times 10^3 \text{ s}^{-1}$) was found to be similar to that of the cyclobutylcarbiny (neutral) radical.⁹

[Reprinted with permission from Ref. 6. Copyright 2005 American Chemical Society.]

When this cyclobutyl-based rearrangement was used as an intramolecular clock to estimate the rate constant for cyclopropyl ring opening via competition experiments (Scheme 5), only a cyclopropane ring-opened product was detected.⁹

Compound $9^{\bullet-}$ undergoes ring opening according to ((4) Reprinted with permission from Ref. 6.

Scheme 5 Intramolecular competition between cyclopropane and cyclobutane radical anion ring opening. [Reprinted with permission from Ref. 9. Copyright 2002 American Chemical Society.]

Copyright 2005 American Chemical Society.). The exocyclic double bond significantly enhances the rate of ring opening (For $R = \text{phenyl}$, an enhancement $>10^3$ was estimated).⁶ This enhanced rate is likely attributable to the increase in ring

Figure 1 Rates of cyclopropylcarbinyll homoallyl-type rearrangements of ketyl radical anions. [Reprinted with permission from Ref. 6. Copyright 2005 American Chemical Society.]

strain resulting from the double bond exocyclic to the cyclopropane ring, rather than to resonance stabilization (the rupturing C–C bond is orthogonal to the π -system of the exocyclic double bond).

[Reprinted with permission from Ref. 6. Copyright 2005 American Chemical Society.]

2.1.4 Cyclopropylcarbinyll → Homoallyl-Type Rearrangements: Structure/Reactivity Trends

Sufficient data is now available to allow a comparison between cyclopropylcarbinyll → homoallyl-type rearrangements of neutral radicals and radical anions generated from ketones ((5)⁶ reproduced by permission of the American Chemical Society). There are certain similarities: (i) radical-stabilizing groups at the α -carbon (R¹) decelerate the ring opening process and (ii) radical-stabilizing substituents on the cyclopropyl group (R²) accelerate the reaction. For both types of processes, relief of cyclopropyl ring strain is not the sole mitigating factor associated with the rates of these rearrangements. Resonance energy (spin delocalization) in the ring-closed versus ring-opened form must also be considered.⁶

[Reprinted with permission from Ref. 6. Copyright 2005 American Chemical Society.]

However, there is an important difference: for radical anions, charge delocalization is at least as important as, and perhaps more important than, spin delocalization (*vide infra*). This interplay between charge and spin delocalization in the ring-closed and ring-opened (distonic) radical anions leads to the reactivity order summarized in Figure 1.⁶

For radical anions generated from aromatic ketones (aromatic ketyls), ring opening of the structurally related neutral (benzylic) radical is much faster. For aliphatic ketones, it is the other way around. Unquestionably, the difference is the ability of the aromatic ring to stabilize the negative charge via resonance (Scheme 6); the numbers refer to Mulliken charges calculated by density functional theory). Clearly, this stabilization of charge is responsible for the low reactivity and thermodynamic stability of the aromatic ketyls.⁹

In contrast, these results show aliphatic ketyls are at least as reactive as (and likely more reactive than) alkyl radicals in β -scission-type processes, despite the fact that the former are

Scheme 6 Aromatic ketyl radical anion with calculated Mulliken charges.

thermodynamically much more stable (by as much as 27 kcal mol⁻¹). Essentially, the O⁻ group, being a potent electron donor, is able to stabilize a radical center. The reason that aliphatic ketyls undergo such rapid rearrangement is that the O⁻ group also stabilizes the double bond in the ring-opened form, possibly to an even greater extent. (An equivalent and indistinguishable argument is that the O⁻ is stabilized by an adjacent radical center in the ring-closed form, and by a double bond in the ring-opened form.) In essence, these systems undergo ring opening at what must be rates comparable to the cyclopropylcarbinyl → homoallyl neutral radical rearrangement because the reactants, products, and transition state are all stabilized by the O⁻ substituent.

Qualitatively and quantitatively, rate constants (k_o) for ring opening of the radical anions can be rationalized on the basis of the thermodynamic stability of the radical anion (which is related to the formal reduction potential of the ketone), the ability of substituents on the cyclopropyl group to stabilize the radical portion of the distonic radical anion (reflected by the C–C bond strength of the cyclopropane), and the stability of the enolate portion of the distonic radical anion (related to the pK_a of the corresponding ketone). A thermodynamic

cycle for estimating the driving force (ΔG°) for ring opening was developed and allowing the nature of the activation/driving force relationship for these rearrangements to be probed. Figure 2 presents a plot of $\log(k_o)$ versus ΔG° for cyclopropylcarbinyl → homoallyl-type rearrangements of both ketyl radical anions and neutral free radicals. Despite the differing structure/reactivity trends discussed above, it is noteworthy that the activation/driving force trends for ring opening of neutral free radicals parallel those of radical anions, although at comparable driving force, ring opening of the radical anions is generally slower.¹⁰

Savéant has developed a theory pertaining to radical anion fragmentations which occur in a stepwise manner (e.g., $R-X + e^- \rightarrow R-X^{\cdot-} \rightarrow R^\cdot + X^-$) that is applicable (6), where $\Delta G^\ddagger_o$ refers to the intrinsic barrier (activation energy at zero driving force) and accounts for the reorganization of solvent and/or counter ion (external reorganization), or changes in the molecule itself (internal reorganization), which are required in order to achieve the transition state; k_B , h , R , and T have their usual meanings.¹¹ When applied to the data in Figure 2, several interesting conclusions emerge. For the radical anions, the intrinsic barrier (12 kcal mol⁻¹) is only slightly higher than that for the neutral free radicals (10 kcal mol⁻¹).

$$\log(k_o) = \log\left(\frac{k_B T}{h}\right) - \frac{\Delta G^\ddagger_o}{2.303RT} \left(1 + \frac{\Delta G^\circ}{4\Delta G^\ddagger_o}\right)^2 \quad (6)$$

Figure 2 Structure/reactivity relationships for the cyclopropylcarbinyl → homoallyl-type rearrangement of radical anions generated from carbonyl compounds and neutral free radical (unshaded data points are based on estimates of k_o).

Assuming that the bond breaking/making contributions to the intrinsic barrier (i.e., internal reorganization energy) are similar for both classes of paramagnetic intermediates, the small difference in rate is attributable to the contribution of a minor, circa 2 kcal mol⁻¹, solvent reorganization component for the radical anion ring opening. This conclusion makes sense because for these ring openings, the negative charge is closely associated with the electronegative oxygen atom in the ring-closed and ring-opened forms, and a major reorganization of solvent is not needed to stabilize the negative charge in the progression from reactant → transition state → product. In contrast, higher intrinsic barriers (circa 16 kcal mol⁻¹) are found for radical anion fragmentations where the negative charge migrates significantly, for example, $\text{Ph}(\text{C}=\text{O}^{\cdot-})\text{CH}_2\text{X} \rightarrow \text{Ph}(\text{C}=\text{O})\text{CH}_2^\cdot + \text{X}^-$.¹²

Scheme 7 Stepwise and concerted dissociative electron transfer. [Reprinted with permission from Ref. 14. Copyright 1998 American Chemical Society.]

There has been a great deal of interest in the current literature in the mechanistic details of dissociative electron transfer (DET), that is, electron transfer that results in bond cleavage. The radical anion ring openings discussed thus far are examples of this phenomenon, and until recently, were all believed to occur in a stepwise manner (Scheme 7, path a). However, it now appears that certain 1,2-disubstituted cyclopropanes undergo concerted, DET (i.e., electron transfer occurs simultaneously with bond cleavage, path b, Scheme 7). The fact that the process is stepwise when $R = \text{Ph}$ as opposed to concerted when $R = \text{CH}_3$ is readily accounted for by resonance stabilization provided by the phenyl group in the former.¹³

2.2 Cyclopropyl Substituted Radical Cation Ring Openings

2.2.1 Aliphatic N-Cyclopropylamine Radical Cations: Structure and Mechanism of Cyclopropane Ring Opening

Compared to the chemistry of radical anion and neutral radical analogs, our understanding of reactivity of cyclopropane substituted radical cations is in its infancy. Kinetic data is virtually non-existent for aliphatic amine radical cations.

Theoretical and experimental studies demonstrate cyclopropylamine radical cation undergoes barrierless ring openings in both gas and solution (Freon) phase.¹⁵ The distonic ring-opened radical cation isomerizes via successive 1,2-hydrogen migration (Scheme 8).^{15,16} Ring-opened cyclopropylamine radical cations preferentially form the radical cation of allylamine **10**.

Notably, ring-opening products undergo further dissociative steps to achieve more stable structures in the gas phase, but not in solution. This difference is presumably attributable to stabilizing interactions with solvent.^{14,15a} Cyclopropylamine radical cations pass through a perpendicular transition state while ring opening occurs. Extremely facile ring opening prevents the molecule from rearranging to the bisected conformation before ring opening. Computational analysis of the relative rates of ring opening for the cyclopropoxyl radical, cyclopropylcarbinyl radical, and cyclopropylaminyl radical cation confirmed barrierless radical cation ring opening is most facile, followed by a preference for ring opening of the cyclopropoxyl radical over cyclopropylcarbinyl radical in a ratio of 3.1×10^6 to 1.^{15b}

The unique structural features of alkylcyclopropylamines likely to govern reactivity and stability were highlighted in electron spin resonance (ESR) and

Scheme 8 Ring openings of aliphatic cyclopropylamine radical cation and subsequent 1,2-hydrogen migration. [Reprinted with permission from Ref. 17. Copyright 1997, American Chemical Society.]

Figure 3 Neutral tricyclopropyl amine adopts a perpendicular conformation; structural reorganization on formation of the radical cation yields a bisected conformation.

computational studies by de Meijere and coworkers. In *N,N*-diisopropyl-*N*-cyclopropylamine, the cyclopropyl group adopts a perpendicular geometry and the molecule has C–N–C bond angles of about 113.3° because the cyclopropyl group prefers to accept electron density into its lowest unoccupied molecular orbital (LUMO).¹⁸ In triisopropylamine, replacement of isopropyl groups with cyclopropanes, results in significant increases in the ionization energy for the radical cation. The ionization energy increased from a value of 7.18 eV for triisopropylamine to 8.44 eV for tricyclopropylamine, as determined experimentally. A similar increase from 7.13 to 8.26 eV was determined by computational work.¹⁸ Generally, trialkylamine radical cations prefer planar orientations that facilitate donation of electron density to the electron deficient nitrogen center.¹⁹ Neutral tricyclopropylamine is significantly more pyramidal than the corresponding radical cation. The cyclopropyl groups in tricyclopropylamine radical cations are in a bisected conformation relative to the N's partially filled orbital. A large structural reorganization from the perpendicular conformation of the neutral analog is required to form the radical cation (Figure 3).^{18,19}

Alkyl substituted analogs typically exhibit conformations where the singly occupied N orbital is eclipsed by a H from an adjacent alkyl substituent affording stabilization by delocalizing spin through hyperconjugative interactions (Figure 4).¹⁹ The preference for the bisected conformation in tricyclopropylamine radical cation means that these hyperconjugative interactions do not exist because the H on the cyclopropane is twisted about 90° from the nitrogen center into a nodal plane of the half filled p orbital.¹⁹ (In the bisected conformation, the cyclopropyl group is a potent π -electron donor.)

While there is much to be learned about the chemistry of aliphatic cyclopropylamine radical cations; it is interesting to note that (i) bi and tricyclopropylamines deviate significantly from the planarity characteristic of the corresponding trialkylamines

Figure 4 Hyperconjugative stabilization characteristic of aliphatic amine radical cations.

and require structural rotations on formation of the radical cation, (ii) these changes likely accompany alignment of the partially filled orbital on nitrogen with the adjacent π system of the cyclopropane, and (iii) ring opening for cyclopropylamines has a low barrier and products undergo further rearrangement in gas phase. Analogous rearrangements do not occur in solution. Taken as a whole, kinetic data available for ring opening of aliphatic cyclopropylamine radical cations comes from computational work and suggests that ring opening is concerted and extremely rapid.

2.2.2 Application: *N*-Cyclopropyl Ring Opening in Ring Expansions of Arylcyclopropanes

Cyclopropane substituted radical cation ring openings are also useful in synthesis. In nonaromatic *N*-cyclopropyl substituted radical cations, the driving force for ring opening is stability imparted by separation of the radical and cation on different atoms, as well as the relief of ring strain. Blackstock and coworkers exploited this in the study of a series of cyclopropylamines (Figure 5), generating the radical cation of the amines via photoinduced-electron transfer.¹⁷

Efficient ring opening, and product formation, was observed for **12** and **13**, although reaction of **13** was slower.¹⁷ The mechanism of these reactions proceed from the N-centered ring-closed radical cation to the ring-opened product that undergoes a subsequent 1,5-hydrogen atom shift (Scheme 9). Intramolecular hydrogen transfer was confirmed via isotopic labeling studies. Subsequent deactivation of the radical ion pair partner 1,4-dicyanobenzene radical anion (DCB^{•-}) via SET is followed by generation of a ketone product through hydrolysis of the neutral ring-opened amines during work up. With the exception of bicyclic compound **14**, these aminocyclopropane radical precursors are used as

Figure 5 Structures of cyclopropylamines investigated as potential precursors to ketones. TIPS = Triisopropylsilyl.

synthetic analogs of enamines, affording high yields of ketones.

2.2.3 Application: Vinyl and Siloxy Substituted Cyclopropyl Ring Opening in Ring Expansions

Chemically induced one electron oxidation of vinylcyclopropanes leads to radical cations that rearrange to the corresponding cyclopentene radical

cations; the rate is much greater than the comparable thermally induced vinyl cyclopropane $\rightarrow$ cyclopentene rearrangement.²⁰ Neither *cis*-1-*p*-anisyl-2-vinylcyclopropane nor *trans*-1-*p*-anisyl-2-vinylcyclopropane undergoes ring expansion to 4-*p*-anisylcyclopentene because the *s*-*trans* radical cation formed cannot ring expand. The former undergoes *cis* $\rightarrow$ *trans* isomerization. In contrast, the spiro compound forms the desired cyclopentene product via a mechanism involving ring opening of the spirocyclic vinylcyclopropane radical cation intermediate (Scheme 10). Similar to the *cis* $\rightarrow$ *trans* isomerizations, the rate of rearrangement is enhanced by SET. Half-lives of 10^{12} min compared to ≤ 1 min were observed for the thermal and SET-induced processes, respectively. SET-induced ring expansion of *cis* and *trans* 1-*p*-anisyl-2-methyl-2-prop-1-en-cyclopropane demonstrates that this chemistry is not limited to structurally rigid cyclopropanes, although it is unclear why these compounds ring expand and the *p*-anisyl-vinylcyclopropanes do not.²⁰

Siloxy cyclopropane radical cations are also key intermediates in synthesis of larger ring systems wherein the radical cation ring opens, without nucleophilic assistance, to a distonic radical cation, and subsequent loss of the silane group forms a β -keto radical.²¹ These β -keto radicals

have proven useful in the formation of polycycles through intramolecular addition to π systems. Transition state calculations by Mattay and coworkers on (bicyclo[4.1.0]heptan-1-yloxy)trimethylsilane determined that endocyclic bond cleavage of the cyclopropane ring occurs.²² This result supports experimental work with analogous compounds, by Hasegawa.²³ Further study of the regioselectivity of the cleavage of the bonds in these bicyclic compounds (Scheme 11) revealed that (i) photochemically induced electron transfer and chemically induced oxidation (by tri-bromophenylaminy radical cation) caused ring opening to occur via different pathways, as evidenced by observed products and (ii) the presence of a nucleophile in chemically oxidized systems enhances the ability of the radical cation to undergo desylation thus increasing reaction efficiency.²³ In addition to utility in synthesis, *N*-cyclopropyl substituted radical cations have been controversial and interesting target molecules for use as mechanistic probes and radical clocks.

2.2.4 Application: *N*-Benzyl-*N*-cyclopropylamine Radical Cation Mechanistic Inhibitors in SET Enzymes

In the late 1970s, the SET mechanism was first invoked to explain irreversible inhibition

Scheme 13 With HAT, hydrogen abstraction yields a neutral carbon-centered radical, which is not expected to ring open. [Reproduced with permission from Ref. 25. Copyright 2006, American Chemical Society.]

of *P450s* by *N*-benzyl-*N*-cyclopropylamine substrates.²⁴ The potential of this class of substrates to resolve controversy between the hydrogen atom transfer (HAT) and SET mechanisms (Schemes 12 and 13), for oxidation of tertiary amines by *P450s* and monoamine oxygenases, stimulated significant interest in mechanistic inhibitors containing cyclopropane moieties to probe for SET in enzymes.^{24b,25} The metabolism of *N*-benzyl-*N*-cyclopropylamine and the 1-methyl substituted analog show similar inhibitory behavior toward *P450* suggesting the hydrogen of the cyclopropane is not involved in inhibition; and further decreasing the probability of HAT for benzylcyclopropylamine.²⁶ Consistently low deuterium isotope effects for dealkylation of tertiary amines by *P450* provided further evidence for the SET pathway.^{27,28}

2.2.5 Application: *N*-Cyclopropylaniline Radical Cations as Mechanism-Based Inhibitors in SET Enzymes

Hanzlik and coworkers set out to demonstrate, using horse radish peroxidase (HRP), that mechanism-based inactivation and ring opening of aryl-*N*-cyclopropylamines occur exclusively through the SET pathway.²⁶ Because HRP's oxidation potential (0.75 V) is less than *cP450*'s (1.7–2.0 V); *N*-methyl-*N*-cyclopropylaniline (which is easier to oxidize) was used in lieu of *N*-methyl-*N*-cyclopropylbenzylamine.²⁶ Products arising from ring opening were detected, although the yields suggested the ring opening pathway accounts for less than 25% of *N*-methyl-*N*-cyclopropylaniline consumed in the reaction. The consumption of this substrate also followed a first order decay indicating inactivation of the enzyme is not occurring to an appreciable degree.²⁶ Radiolabeled cyclopropylaniline inhibitors (Figure 6) and radical traps were employed to determine the fate of the cyclopropyl group. In HRP, trapped products were unambiguously ascribed to SET.²⁶ Products derived from HRP oxidation of *N*-methyl-*N*-cyclopropylbenzylamines **15**, **19** suggested a unimolecular rearrangement, as different products are expected from a nucleophile-assisted ring opening.^{24b} In contrast, both *N*-methylaniline **16** and *N,N*-dimethylaniline **17** undergo deprotonation of the *N*-methyl group after SET.²⁶ In *P450* neither inhibition nor ring opening products were observed with *N*-methyl-*N*-cyclopropylanilines **18**.²⁵ Experiments with *P450* and the *N*-benzyl-*N*-cyclopropylamines produced the ring-opened metabolite of the SET pathway in 57% yield!²⁵ Interestingly, analogous investigation of *N*-methyl-*N*-cyclopropylbenzylamine was first order showing no inhibition or

ring- opened product; rather dealkylation to form *N*-cyclopropyl-*N*-benzylamine was observed.²⁵

Key to the viability of aromatic *N*-cyclopropyl substituted amines as mechanistic inhibitors is validation that (i) ring opening is competitive with other modes of decay for the radical cation, such that inhibition due to ring opening occurs with a frequency that can be easily detected relative to normal modes of catalysis and (ii) ring opening and the resultant enzymatic inhibition are irreversible processes.

2.2.6 Cyclopropane Ring Opening in Chemical Systems: *N*-Cyclopropylaniline Radical Cations

A comprehensive understanding of all factors that govern the mechanism, kinetics, and energetics of cyclopropane radical cation reactions, as well as the relative propensity of these oxidized species to decay by one pathway or another, is integral to unlocking their potential as mechanistic inhibitors, radical clocks, and photosensitizers. Recently, our group studied the ring opening of electrochemically generated *N*-methyl-*N*-cyclopropylaniline radical cations, and curiously, ring opening occurred much slower than deprotonation.²⁹ On the basis of the variation of peak potential with sweep rate and concentration, it was concluded that decay of the radical cation is first order (as expected for a ring-opening process). Notably, decay is zero order in CH₃OH, which effectively rules out the nucleophile-assisted pathway for Nu[−] = CH₃OH.²⁹ Indirect electrochemical studies using various substituted ferrocenes were performed, and in all cases, the kinetics were controlled by the chemical step (i.e., cyclopropane ring opening). These two sets of experiments enable both the oxidation potential (+0.528 V vs 0.1 M Ag⁺/Ag) and the rate constant for ring opening

Figure 6 Structures of aryl cyclopropylamines investigated in enzymatic systems.

($k_o = 4.1 \times 10^4 \text{ s}^{-1}$) to be resolved.²⁹ Laser flash photolysis (LFP) experiments (direct photoionization at 266 nm) showed that the radical cation of *N*-cyclopropyl-*N*-methylaniline was detected at a λ_{max} of 480 nm, and the lifetime for the radical is not perturbed on introduction of a *N*-cyclopropyl group (in place of an *N*-methyl) suggesting that ring opening occurs on a time scale too long for LFP, meaning that k is less than $1 \times 10^6 \text{ s}^{-1}$.²⁹ Thus, rather than being more easily oxidized, *N*-cyclopropyl-*N*-methylaniline is actually slightly more difficult to oxidize than *N,N*-dimethylaniline ($E_{\text{ox}} = +0.491 \text{ V}$). The sluggish rate of ring opening, and the fact that the cyclopropyl group seems to have exerted little effect on the oxidation potential is easily explained; in *N*-cyclopropyl-*N*-methylaniline radical cation, the perpendicular conformation is lower in energy than the bisected conformation.²⁹ In the perpendicular conformation, overlap between the highest occupied molecular orbital (HOMO) of the cyclopropyl group and adjacent π -system is minimal.²⁹ Thus, the radical cation does not enjoy thermodynamic stabilization afforded by the cyclopropyl group, and is in the wrong conformation for ring opening to occur. This system is of particular interest because *N*-cyclopropyl-*N*-methylaniline and several structurally related derivatives were

used to probe for SET in amine oxidations mediated by *P*450. Information regarding the low rate and unfavorable stereoelectronic factors for ring opening was not available for these studies.^{5, 13–16, 18} On the basis of this new information, it is likely that even if electron transfer were occurring in these systems, the sluggish rate of ring opening would be unable to compete with other processes such as radical cation deprotonation (Scheme 14).

N-Alkyl-*N*-cyclopropylaniline radical cations have been employed as mechanistic probes in nitrosations of aromatic amines where ring opening is an indicator of radical cation intermediates in nitrosation of *N,N*-dialkyl aromatic amines. Nitrosation of *N*-alkyl-*N*-cyclopropylanilines in acidic media (Scheme 15) proceeds through an aminyl radical cation intermediate. This intermediate undergoes regioselective ring opening and reacts further to form *N*-alkyl-*N*-nitroanilines.³⁰ Studies of acidity effects on decomposition pathway revealed the preferential mode of reactivity is de-ethylation (vs de-methylation) when solution pH is above 2.³¹ With addition of base, α -deprotonation emerges, a favored pathway of decay; when the acidity is high, deprotonation is suppressed and *N*-alkyl-*N*-cyclopropylanilines ring opening dominates.

Scheme 14 Ring opening and deprotonation are noncompetitive for *N*-methyl-*N*-cyclopropylaniline radical cations.

2.2.7 Cyclopropane Ring Opening in Chemical Systems: Cyclopropylarene Radical Cations

In the past decade, kinetic studies of arylcyclopropane radical cations have emerged shedding light on their reactivity.^{12,23,25–28,32} One very notable feature of cyclopropylaryl compounds is the stability provided by cyclopropanes in the plane of the π system containing the radical.³³ Crystallographic data in addition to molecular mechanics calculations for several aryl cyclopropane radical cations suggests cyclopropanes can act as electron donors when the cyclopropane is in the bisected conformation (Figure 7).

The equilibrium conformation for cyclopropyl naphthyl and phenyl compounds is bisected while the 9-anthryl compounds adopt a perpendicular geometry (Figure 8).³³ The cyclopropylanthracenes are forced into this conformation by unfavorable steric interactions between the cyclopropane and peri-hydrogens on the adjacent anthracene. For the naphthyl and phenyl compounds the preference for the bisected conformation enables interaction of the aryl groups' π system with the sp^2 orbital of the cyclopropyl carbon.³³ When the molecule is strongly electron deficient, as in the case of a radical cation, the p orbital on the aryl carbon adjacent to the cyclopropane is twisted out of conjugation, with

Figure 7 Walsh model for the cyclopropane HOMO in the bisected conformation mixes with the LUMO of the aryl group, also coplanar, allowing it to donate electron density to the conjugated ring. [Reprinted with permission from Ref. 33. Copyright 1990 American Chemical Society.]

Figure 8 Cyclopropylarenes.

the cyclopropane in the perpendicular conformation, markedly decreasing propensity for ring opening.³³

Dinnocenzo *et al.* demonstrated that ring opening of phenylcyclopropane radical cation occurs via a nucleophile-assisted, overall second-order process as delineated in ((7))³⁴ in part with permission from Ref. 34. Copyright 1997 American Chemical Society).

[In part with permission from Ref. 34. Copyright 1997 American Chemical Society.]

Inversion of configuration was observed in the nucleophile-assisted ring opening of 1-phenyl-2,3-dimethylcyclopropanes, phenylcyclopropane reacting with methanol, isopropanol, *tert*-butanol, pyridine, water, and cyanide ion.^{34,35} Stereoinversion is attributed to positive overlap between the nonbonding orbital of the nucleophile and the σ^* orbital of the radical cation's one electron bond favoring a backside (σ^*) rather than frontside (σ) interaction.^{35,36} Interestingly, the rate constants in Table 1 for substitution on 1,1-diphenylcyclopropane translate to a reactivity ratio 5:3:1, or less, going from primary to tertiary alcohol.^{35a}

Structural distortion inherent to radical cations formed by one electron oxidation leads to an early transition state with a large carbon–nucleophile distance lessening the effect of the nucleophile's steric bulk on kinetics.^{35a} Additionally, the electronic environment of the carbon is significantly more important in determining the site of substitution than in four electron S_N2 reactions.

Table 1 Rate constants for ring opening of phenylcyclopropane radical cation by various nucleophiles at 23 °C.

Nucleophile	k , ($M^{-1}s^{-1}$)
CH_3OH	1.6×10^7
CH_3CH_2OH	1.4×10^7
$(CH_3)_2CHOH$	1.1×10^7
$(CH_3)_3COH$	0.73×10^7

Rate constants in Table 2 for the reaction of 1,1-diphenyl-2-alkylcyclopropane radical cations present a counter intuitive trend in that reaction kinetics actually increase as the degree of substitution is increased at the site of attack.

The preference for anti-Markovnikov addition of methanol to substituted cyclopropanes was quite accurately predicted to be a result of weakening but not breaking of the C_α–C_β bond by Hixson and coworkers.³⁸ Much later, this supposition was confirmed by computational work that showed the C_α–C_β bond is about 10 kcal mol⁻¹ in the transition. Further, it is noted that displacement preferentially occurs at the more substituted carbon.³⁷ Enhanced stabilization of the positive charge in the transition state on the more substituted carbon primarily drives the reaction to proceed at the more sterically hindered, but more electron rich, carbon on the cyclopropane ring as shown in Scheme 16.³⁷

In the transition state, increased C_α–C_β bond length, a 140° C_α–C_β–OMe bond angle, and a greatly increased localization of positive charge at the β position are predicted by both AM1 and PM3 calculations.^{35b} The latter feature predicts the observed positive ρ value and high degree of correlation between *k* and the Hammett σ⁺ (rather than σ) parameter. *p*-Substituted phenyl groups at C_α stabilize the positive charge decreasing the importance of substitution at the C_β attack site

**Scheme 16** Methanol adds at the more substituted carbon on an alkylsubstituted cyclopropane radical cation. [Reprinted with permission from Ref. 30b. Copyright 2000, American Chemical Society.]

on the cyclopropane effectively, reintroducing the issue of steric bulk at the site of substitution, and leading to an increased barrier to reaction as shown by the rate constant trend in Table 2. Although the structures of neutral cyclopropanes are relatively unresponsive to alkyl substitution, their radical cation counterparts are far more sensitive.

Cyclopropylbenzene and cyclopropylnaphthalene radical cations undergo nucleophile-assisted ring opening,^{35,39} whereas radical cations derived from cyclopropylanthracenes do not undergo ring opening.³⁹ Surprisingly low rate constants for ring opening of cyclopropylnaphthalenes have been observed, on the order of 10 M⁻¹ s⁻¹. The decay occurs via a bimolecular pathway where the barrier to reaction is significantly affected by the magnitude of the positive charge on the cyclopropane in the transition state.⁴⁰ The ring openings of the analogous radical anions are unimolecular processes with rate constants several orders of magnitude larger (10⁶–10⁸ s⁻¹) than those observed for the aforementioned radical cations.⁴¹ Electrochemically generated 9-cyclopropylanthracene and 9-bromo-10-cyclopropylanthracene radical cations show that nucleophilic attack on the aromatic ring occurs, rather than a nucleophile-assisted ring opening, in the presence of methanol.^{40b} While some cyclopropane ring-opened products were observed, in these studies, ring-opened products were shown to arise from reaction of a primary product during work up of the reaction mixture.^{40b}

A thermochemical cycle was used to estimate Δ*G*^o showing nucleophile-induced ring opening is extremely exothermic for all these radical cations (Δ*G*^o = –39, –28, and –20 for Ar = phenyl, α-naphthyl, and 9-anthryl, respectively). These results rule out the explanation that the sluggish rate of ring opening associated with the α-naphthyl and 9-anthryl systems is simply attributable to the enhanced stability of these radical cations. Two major factors were found to contribute to Δ*G*₀ for ring opening: (i) the ability of the aryl group to stabilize the ring-closed radical cation (related to *E*_{Ar⁺/Ar}⁰) and (ii) the ability of the aryl group to stabilize the radical portion of the ring-opened (distonic) radical cation. On this basis, it was suggested that the reason that ring opening is slow for arylcyclopropane radical cations is a late (product-like) transition state, Figure 9, in which the positive charge is localized on the cyclopropyl group and

Figure 9 Charge localized transition state for ring opening of cyclopropylarenes. [Reprinted with permission from Ref. 35b. Copyright 1997 American Chemical Society.]

thus, unable to benefit from stabilization offered by the aromatic ring.

The aromatic ring stabilizes the radical portion in the transition state; however, the effect of the aryl group on radical stability is miniscule compared to the effect of the aryl group on the stability of the ring-closed radical cation. (In the case of 9-cyclopropylanthracene radical cation, stereoelectronic factors may also contribute to the high barrier to ring opening; the cyclopropyl group in this system may exist in the perpendicular conformation, which does not meet the stereoelectronic requirements for ring opening.) For a cyclopropane containing compound to act as an effective probe, for a SET mechanism with a radical cation intermediate, ring opening must occur faster than other possible decay processes. In the case of these radical cations the reactions proceed slowly through a product-like transition state with significantly localized charge, which severely limits their reactivity and dominates over the large thermodynamic stabilization that would otherwise suggest these molecules would make attractive substrates for use as mechanistic probes or radical clocks (see **Radical Kinetics and Clocks**).⁴²

B3LYP calculations with a 6-31G(d) basis set suggest the structure of phenylcyclopropane radical cation has a cyclopropane containing two long and one normal length bond in contrast to the one long two normal bond length configuration observed for the alkylsubstituted cyclopropanes in Figure 10.^{35b} Additionally, with alkyl substitution at the β position the bisected conformation

Figure 10 Substituted cyclopropanes studied in computations.

of the phenyl ring (which in the unsubstituted compound overlaps and stabilizes the two C–C σ bonds relatively equally) moves into a conformation with a higher degree of overlap with the longer C_α – C_β bond. Redistribution of charge accompanies these structural changes because the alkyl substituents are capable of stabilizing more of the positive charge associated with the radical cation character.^{35b}

Photochemically generated three-ring-bridged allylcyclopropane radical cations undergo nucleophilic substitution in the presence of base. These substitution products are arrived at through a deprotonation mechanism, Scheme 17.⁴³ Deprotonation products are favored at position 2 because of resonance stabilization afforded by interaction with the neighboring functional groups.⁴³

Like nucleophile-assisted ring openings, the cis–trans isomerization of 1,2-disubstituted cyclopropane radical cations proceed through ring-opened intermediates. These isomerizations proceed by different mechanisms when the initial one electron oxidation to form the ring-closed radical cation is induced photolytically or by a chemical oxidant.⁴⁴ The latter process (Scheme 18) is significantly more facile; the chemical oxidation of 1-phenyl-2-vinyl-cyclopropane by p -BrPh₃N⁺ SbF₆[–] experiences a rate increase of 10^{24} relative to the thermal process.^{44a}

Furthermore, the chemically induced oxidation does not involve the biradical intermediate (Figure 11) implicated in the photochemical reaction, although both reactions do proceed through a ring-opened intermediate.^{44,45} The involvement

Scheme 17 Allyl cyclopropanes deprotonation of the radical cation intermediate at position 2.

Scheme 18 Isomerization proceeds via ring openings of 1,2-disubstituted cyclopropane radical cation. [Reprinted with permission from Ref. 37. Copyright 1993, American Chemical Society.]

Figure 11 Biradical intermediate characteristic of isomerization of photochemically generated 1,2-disubstituted cyclopropane radical cation.

of the biradical intermediate is easily eliminated in chemically induced isomerization as it is exothermic by only $0.7 \text{ kcal mol}^{-1}$ and 32 kcal mol^{-1} are needed to form the biradical (estimated to be equal to the enthalpy of activation for the thermal process).^{44a}

The chemically oxidized cyclopropane isomerizes through a ring-opened distonic radical cation intermediate. The reaction mechanism involves rotation at both stereocenters in a noncorrelated way as shown in Scheme 19. These mechanistic conclusions are supported by isotopic labeling studies that show both possible trans products are formed. NMR analysis of the reactions proved that this is not a pre- or post-reaction equilibrium. Additionally, accelerated isomerization of the chemically generated cyclopropane radical cation results from a

decreased propensity to undergo back electron transfer thus favoring the competing isomerization.^{44a} Additional reactions of chemically and photochemically generated cyclopropane radical cations have been reported to be involved in cycloaddition reactions, although that is outside of the scope of this review as these mechanisms may involve ring intact intermediates.⁴⁶

2.3 Comparison of Trends for Neutral Cation and Anion Radicals of Cyclopropane Substituted Compounds

The use of substituted cyclopropane substituted radicals and radical ions as mechanistic probes hinges largely on our understanding of their reactivity. Some notable parallels can be drawn from comparison of cyclopropane radicals, radical anions, and radical cations ring openings. Alkyl radicals undergo rapid ring openings like their ketyl radical anion analogs. In some cases, the ketyl radical anion ring openings are more facile because the oxygen is

Scheme 19 Chemically oxidized 1-phenyl-2-vinyl-cyclopropane radical cation isomerization through a ring-opened intermediate. Rotation at both stereo centers yield both trans products.^{44a}

a potent electron donor that can very effectively stabilize the ring-opened product and transition state. While similar kinetic data is not available for aliphatic cyclopropyl radical cations, computations show that alkyl substitution can induce conformational changes in order to facilitate interaction and stabilization of charge. Similarly, no experimental kinetic data is available for aliphatic amine radical cations but computations suggest that aliphatic aminyl radical cations ring open extremely rapidly and the ring-closed form may not exist as a discrete species. Moreover, trialkyl amines that adopt planar conformations maximize interactions of substituents with the radical center. Introduction of cyclopropyl groups induces conformational changes placing the cyclopropane in a bisected conformation facilitating ring opening and delocalizing spin through hyperconjugative interactions. In aliphatic radicals, ketyl radical anions, and aliphatic radical cations a substituent's ability to stabilize charge has important thermodynamic implications. In aminyl radical cations and ketyl radical anions charge stabilization is an important kinetic consideration as well. In aliphatic cyclopropylamine radical cations, the ring-closed radical cations prefer a bisected conformation but the ring-closed form may not represent a potential energy minima and ring opening may proceed through a perpendicular transition state. Contrastingly, in aromatic cyclopropane cation radical systems significant evidence exists to suggest specific stereoelectronic requirements; that is, a planar bisected conformation of the ring relative to the adjacent π system is necessary for ring opening to occur. These stereoelectronic constraints along with the enhanced radical cation stability afforded to the ring-closed form by the aryl group lead to a markedly decreased propensity for ring opening of aryl (vs aliphatic) substituted cyclopropanes. These reactions proceed through a late transition state; therefore, spin and charge delocalization in the reactant is not offset by similar stability in the transition state; in the transition state the charge is highly localized. Moreover, the perpendicular conformation of the reactant is more thermodynamically stable than the bisected conformation necessary for ring opening. The phenyl cyclopropyl radical anion ring openings rate constants are similarly depressed and for similar reasons, highlighting the importance of resonance energy in the radical anion process as well. Substitution of electron-donating groups on the cyclopropyl ring stabilizes the radical in the product

causing a several order of magnitude increase in rate constant and again demonstrates the importance of spin delocalization. In all cases (radical anion, radical cation, and neutral radical) relief of ring strain and delocalization of spin can drive ring opening. For both cyclopropane radical cations and radical anions, delocalization of charge also affect reactivity significantly. In the case of the radical cations, stereoelectronic requirements for ring openings, particularly in the aryl cyclopropanes, will dictate whether ring opening is a favorable process.

3 Δ -5-HEXENYL RADICAL/RADICAL ION CYCLIZATION

3.1 Δ -5-Hexenyl Radical Cyclizations

The Δ -5-hexenyl radical reaction is the most widely studied radical cyclization mechanism. This is not surprising, as the stereo and regio selectivity of related intramolecular additions make such reactions extremely attractive from a synthetic perspective. Additionally, the Δ -5-hexenyl radical finds use as a radical clock and a mechanistic probe (see **Basic Concepts on Radical Chain Reactions and Radical Kinetics and Clocks**).⁴⁷ This reaction is known to be kinetically controlled for reasons discussed in the preceeding section. While extensive kinetic characterization of the corresponding 5-hexenyl radical anion cyclization has not been performed; product ratio analysis allows parallels between the two processes to be drawn. The next few pages show that the reactions of 5-hexenyl radicals and their corresponding radical anions proceed similarly.

It is well established that the Δ -5-hexenyl radical preferentially undergoes intramolecular addition via the 5-*exo*-trig rather than 6-*endo*-trig pathway to yield the thermodynamically unfavorable product (Scheme 20).⁴⁸ The 6-*endo* product is stabilized relative to the 5-*exo* product because it is a more substituted radical with less ring strain. In spite of thermodynamics; the *exo* product occurs in 98 to 2 percent excess over the *endo* product.⁴⁹

The pathway to the *endo* product proceeds through a boat-like transition state whereas the *exo* cyclization proceeds through a less strained chair-like transition state (Figure 12) that has been shown to be 2.8 or 1.7 kcal mol⁻¹ lower in energy than the *endo* transition state (by calculation and

Scheme 20 Δ -5-Hexenyl radical cyclization.

experiment, respectively).⁴⁵ The chair conformation maximizes orbital overlap, thereby imposing a stereoelectronic demand for exo cyclization.

Table 3 shows the 5-hexenyl cyclization was more facile than cyclization of larger chains and more endo selective. Comparing an alkyne and alkene, addition is more facile for the alkene and more regioselective for the alkyne.

3.1.1 Regioselectivity of Δ -5-Hexenyl Radical Cyclization

Functionalization of the terminal end of the alkene, and the corresponding polarization of the scissile

double bond, markedly affects kinetics and the preference for endo or exo cyclization. The 5-hexenyl radical is nucleophilic and polarization of the double bond affects preferential site of addition. The attraction between the nucleophile and the most electrophilic site on the cleavable double bond favors reaction through the more strained transition state structure and forms the thermodynamic product. Stabilizing groups at the exo attachment site introduce a steric effect which makes both regioisomers equally likely (Table 4). The endo selectivity is increased when a methyl group is present at the endo attack site.

Geminal substitution increases k relative to the unsubstituted 5-hexenyl reaction (Table 5). The maximum effect was observed for the 3 position. The rate constant for the 1-substituted compound is lower than those for the other substituted compounds in Table 5 because it involves cyclization of a secondary radical. Conversely, substitution of electron-withdrawing groups at or near the radical site increases radical nucleophilicity and rate constant for cyclization. Donation of electron density to the radical decreases the rate and decreases selectivity. Substitution of a $\text{Si}(\text{CH}_3)_2$ for the two carbon stabilizes the radical to such an extent that it becomes exo selective.

3.1.2 Stereoselectivity of Δ -5-Hexenyl Radical Cyclization

Substitution not only plays a role in regioselectivity but also dictates stereoselectivity for these cyclizations. For 5-hexenyl radicals, substitution at the 1 or 3 position leads to the cis product while

substitution at the 2 or 4 position favors the trans product (Figure 13). Generally, substituents in the 2, 3, or 4 position prefer a chair-like transition state placing bulky substituents in a pseudoequatorial position. Moreover, selectivity increases with geminal disubstitution at the 3 position.⁵⁰ Rate data for cyclization of various methyl substituted 5-hexenyl radicals is presented in Table 6. Placing substituents in an axial position is disfavored by destabilization imparted by Van der Waals interactions, bending, and torsional strain in the transition state. Methyl substitution at the radical center leads to increased stereoselectivity. Similar substitution near the cissile alkene bond enhances production of the trans product. Interestingly, the strain energy of the transition state, assuming a chair conformation for both the stereoisomers, overestimates the cis contribution. The experimental partitioning ratio for the cis and trans products is in good agreement with computational work where the trans isomer proceeds through a boat-like transition state.

Rate data for cyclization of alkenylaryl compounds (Table 7) showed the rate constants for these reactions to be three to four orders of magnitude greater than for the corresponding alkenyl reactions.

**Figure 13** Isomeric products for cyclization of 1-*t*-butyl-5-hexenyl radical cyclization.

These aryl radicals are subject to lesser torsional strain and less energy is required to form the new bond. The aromatic radicals are isolated in an orbital adjacent to the π system. The corresponding ether exhibits an order of magnitude increase in rate constant. Substitution of the electrophilic double bond for the aryl ether causes a moderate decrease in the cyclization rate constant relative to the unsubstituted double bond.

In 1-methyl-5-hexenyl radical cyclization, the cis product is obtained because stabilizing torsional interactions between the methyl and C6 outweigh the strain imposed by bending. For many years, replacement of the methyl with a more sterically bulky group, such as *t*-butyl, was believed to introduce unfavorable Van der Waal interactions that would dominate torsional and bending effects and calculations suggested subsequent cyclization would preferentially form the trans product (Figure 13). On reinvestigation, Curran and others were able to show that both experiment and higher level computational analysis evidenced a preference for the cis product.⁵⁰

Comparing molecular mechanics and quantum mechanical calculations it was noted that only the latter computation accurately predicts the cis product preference, thus providing a basis for the assertion that both steric and electronic factors contribute to determination of product stereochemistry.⁵⁰ It has been noted in competition experiments that yields are affected by alkyl substitution of the cissile bond; with more cyclized product forming when the 5-hexenyl radical is more highly substituted.

3.1.3 Solvent Effects on Δ -5-Hexenyl Radical Cyclization

In some cases, as solvent polarity is increased the cis isomer becomes more predominant; notably, this is not the case for all hexenyl radical cyclizations

Table 6 Effects of substitution on stereoselectivity of 5-hexenyl radical cyclizations at 25 °C.

in Table 8. The stereoselectivity of the cyclization of the 2,2-dimethyloct-en-3-yl radical exhibits a moderate dependence on solvent polarity. Similar trends have been observed for the hept-6-en-2-yl and the 1,1,1-trifluorohept-6-en-2-yl radical. The proportion of cis isomer increases with increasing solvent dipole moment, results being likely indicative of a polar transition state.⁵⁷

3.2 6-Hepten-1-one Radical Anion Cyclizations

Similar 6-hepten-1-one radical anion cyclizations ((8) reproduced from Ref. 66. Copyright 1989,

American Chemical Society) have been investigated for their potential use in synthesis of cyclic molecules as well as intramolecular radical clocks; not unlike their neutral radical analogs.⁶⁷

[Reproduced from Ref. 66. © 1989, American Chemical Society.]

The dimethylpyrrolidinium (DMP) mediated reduction of substituted 6-hepten-1-ones shows these radical anions undergo regioselective cyclization to form the exo product, similar to the neutral radical analog. The analogous direct reductions of 6-hepten-1-ones form straight chain alcohols, not the cyclized alcohols characteristic of the mediated process. These products are thought to form because, at the oxidation potential of the direct reduction, the radical anion can undergo subsequent reduction to the dianion. The dianions of these ketones do not prefer the cyclization pathway.⁶⁶ Heterogeneously catalyzed reduction of *o*-(3-butenyl)fluorobenzene exhibits regioselectivity similar to that observed for the aforementioned ketones.⁴⁷ The initial steps of the

3.2.1 Regio/Stereoselectivity of 6-Hepten-1-one Radical Anion Cyclizations

These radical ion cyclizations are known to be endo selective, reminiscent of a 5-hexenyl radical cyclization. The primary product of the radical ion reaction for analog **20** is **21**, which is expected to result through nucleophilic attack on the less sterically crowded face of the molecule.⁶⁷ Two isomeric radicals result; the trans radical leads to the minor product **22** because of an inability to undergo further cyclization ((9) reproduced with permission

Other ketones **23–26**, shown in Figure 14 are also reduced by DMP to yield radical anions exhibiting similar regio- and stereospecificity in cyclization.⁶⁷

Swartz and coworkers astutely noted that the plot of product yield as a function of molar equivalents of electrons consumed exhibits a linear relationship with a slope on the same order of magnitude as the previously reported rate constant for the corresponding cyclizations for both hexenyl and hexynyl radicals.⁶⁸ Moreover, **26** shows a retardation in rate constant of about an

Figure 14 Structures of ketones known to undergo mediated reduction and subsequent cyclization.

order of magnitude, as indicated by the analogous plot; this result is cogent as cyclization onto an arene would be expected to be subject to a rate decrease.

The reductive cyclization by DMP is highly stereoselective.⁶⁸ The homogeneously catalyzed reduction of 6-hepten-2-one has been shown to be sensitive to the concentration of water while the heterogeneous process is not. The heterogeneous process is extremely stereoselective, so even if it was subject to an analogous effect it would be difficult to discern an increase in stereoselectivity that was statistically significant. Unlike the heterogeneous process the ratio of cis to trans product formed for the homogeneously catalyzed reduction can be increased by changing the concentration of water or catalyst or by using a different redox catalyst all together.

A similar mechanism is invoked to explain the homogeneously and heterogeneously catalyzed processes. The two mechanisms are differentiated by the reversibility of the cyclization step in the homogeneously catalyzed system. The observation of an appreciable amount of the thermodynamically favored product in the homogeneously catalyzed reaction results from differences in how the catalysts function.⁶⁶ The insoluble heterogeneous catalysis complex will form the kinetic product at the electrode surface by extremely rapid subsequent irreversible reduction of the cyclized product.⁶⁶ Contrastingly, in the homogeneous system, the proportion of the product going to the kinetic product will be proportional to the concentration of catalyst in solution.⁶⁶

3.3 Stereo- and Regiochemical Trends for Δ -5-Hexenyl Radicals and Radical Anions

Comparatively, the radical anion and radical processes exhibit similar regio- and stereoselectivity in cyclization. Generally, both reactions undergo exo ring closure and preferentially form the cis product. Of course, substituent effects and electronic effects lead to exceptions in both cases. Little kinetic data exist for the radical anion process but it has been proposed that the two processes occur through a similar step in their mechanisms, cyclization through the neutral radical center. Swartz suggests that the radical anion process is expected to occur with similar rate constants to Beckwith's measured ones for 5-hexenyl cyclizations. For the radical anion reactions the catalyst used is known to be a factor that could potentially allow for selective production of the thermodynamic product. For the neutral radical, the most favored transition state resembles the cyclohexane chair conformation, maximizes overlap between the singly occupied orbital containing the radical and the π^* orbital of the atom being attacked, and minimizes ring strain in the transition state. Steric factors have been shown to play some role in both processes with steric demands and the placement of bulky groups in the transition state modulating stereochemistry of the products and kinetics of the cyclization. In some 5-hexenyl radical cyclizations, increasing solvent polarity increases the preference for the cis product, although this is not true for all 5-hexenyl radical cyclizations. In light of the available evidence, it is reasonable to conclude that the neutral radical and the radical ion cyclization may proceed through similar transition states. This may indicate that, unlike the previously discussed cyclopropane ring openings, charge delocalization in the transition state is not a primary factor in determining reactivity. Similar to the cyclopropanes, this may result from the stabilization afforded by the oxygen on the ketyl radical anions. Of course, these suppositions are simply those without further investigation of the radical anion reactions. Understanding the nature of the transition state for these intramolecular additions as well as determination of important kinetic parameters has facilitated their use in stereo- and regioselective synthesis of cyclic compounds. Moreover, knowledge of the kinetic parameters for these reactions can aid in determination of useful kinetic parameters for other interesting reactions by acting

as intramolecular radical clocks. One class of reactions where radical clocks like these are useful is in atom and group transfer reactions (see **Halogen and Chalcogen Transfer Chemistry**). The forthcoming section addresses a particularly interesting class of atom transfers, namely, deprotonation and hydrogen transfer reactions.

4 MECHANISMS OF HAT

4.1 Modes of HAT

The most common, and seemingly simple, atom transfer reaction involving radicals is hydrogen transfer (see **Radical Rearrangements: Ester-Substituted Radicals and Hydrogen Atom Migrations**). The equivalent process for a radical cation is deprotonation. HAT reactions are an extremely interesting class of radical reactions, finding widespread importance in both synthesis and biology.

Classical HAT is characterized by the simultaneous removal of a proton and one electron from the breaking bond. As of late, several authors report evidence suggesting alternative routes for HAT involving radicals and radical ions such as sequential proton loss electron transfer (SPLET), electron transfer followed by proton transfer (ET/PT), and proton-coupled electron transfer (PCET).⁶⁹ Classical concerted HAT proceeds via direct transfer of a hydrogen atom between molecules via a three-electron transition state as shown in Scheme 22.

4.1.1 Classic HAT

Many HAT reactions including the reaction of the *N*-hydroxylphthalimide radical (PINO[•]) with toluene and several other aliphatic and aromatic hydrocarbons proceed via classical HAT.⁷⁰ Since proton and electron transfer occur in a single molecular motion via a three-electron transition state, neither will individually affect the rate of

Scheme 22 Concerted hydrogen transfer.

reaction. Instead, the rate is directly related to relative difference in the strength between the breaking and forming of the bond. The relationship between reaction kinetics and bond dissociation energy is quantified by the Evans Polyani Principle; a nice example of this is the HAT from hydrocarbons to phthalimide *N*-oxyl radical (PINO[•]) in acetic acid.^{70,71} For this process, a reasonably linear correlation is noted with an α value of about 0.38 denoting a slightly exothermic process.⁷¹ The Evans Polyani Equation is not well suited to represent the relationship between kinetics and thermodynamics of reactions when factors such as stereoelectronic effects, steric effects, and polar effects influence enthalpy since these variables are not considered in the corresponding equation.⁷² One example where stereoelectronic factors significantly impact kinetics is in the reactions of the 1-hydroxy-benzotriazole radical (BTNO[•]) with cyclic and acyclic alkylarenes. Bond scission is more facile in the former case as a result of hyperconjugative interactions between the breaking C–H bond and the aromatic system; these interactions weaken the C–H bond.⁷³

4.1.2 Electron Transfer Followed by Proton Transfer

One sequential alternative to classical HAT is the electron transfer followed by proton transfer mechanism. Studies of the reaction of several para-substituted dimethylanilines with PINO[•] indicate sequential electron transfer, proton transfer is a probable mechanism for HAT as shown in Scheme 23.^{69e}

Baciocchi asserts differences in isotope effects observed for dideuteromethyl and monodeuteromethyl *N,N*-dimethyl anilines suggest that electron transfer and proton transfer are not concerted. The intermolecular isotope effects observed for the former compounds were smaller than those observed for the corresponding monodeuteromethyl amines. Kinetic isotope effect (KIE) studies showed large primary isotope effects for monodeuteromethyl amines with electron-withdrawing para substituents.^{69e} In addition, the overall rate is also highly dependent on the electron-donating ability of the substituent. Furthermore, the intramolecular KIEs are larger than the intermolecular ones, suggesting that

Scheme 23 ET/PT mechanism for the reaction of PINO radical with *N,N*-dimethylanilines. [Reprinted with permission from Ref. 74. Copyright 2005 American Chemical Society.]

removal of the hydrogen atom is not necessarily the rate determining step. These observations suggest electron transfer is followed by proton transfer. Electron transfer was shown to be rate limiting for substrates having electron-donating substituents; whereas proton transfer could affect the rate for electron-withdrawing substituents. Insomuch as electron-donating substituents on a particular compound should correspond to a more favorable and consequently exothermic process, the rate of reverse electron transfer is expected to be significantly less than the favored deprotonation.^{69e} The magnitude of intramolecular deuterium isotope effect results from the decay route of the electron transfer product, either back electron transfer or deprotonation. For strongly electron-donating substituents, no intramolecular isotope effects were observed, further supporting a rate limiting electron transfer. Contrastingly, for electron-withdrawing substituents, back electron transfer is expected to proceed faster as these substituents pull electron density from the radical cation making it less able to stabilize the electron deficiency of the nitrogen.^{69e} In studying these particular compounds, it is noted that significant intermolecular isotope effects emerge alluding to the significance of proton transfer in the rate of these reactions.^{69e} A similar mechanism was observed in the reaction of benzotriazole *N*-oxyl radical reactions with para-substituted *N,N*-dimethylanilines.⁷⁴ In contrast to this sequential process, previous studies by Espenson of deprotonation on phenols and several hydrocarbons suggest concerted HAT mechanisms with PINO^{70,71,75}

4.1.3 Sequential Proton Loss Electron Transfer

A second sequential mechanism proposed for HAT is SPLET. The SPLET mechanism was first proposed by Ingold and coworkers to explain a solvent induced effect on rate of deprotonation of phenols by 2,2-diphenyl-1-picrylhydrazyl radical (dpph').⁷⁶ In studying the kinetics of these reactions, the authors observed a drastic increase in rate constant for hydrogen abstraction from phenols by dpph' in solvents with the ability to hydrogen bond to the phenol.⁷⁷ Moreover, studies in alkane solvents showed decreased rate constants, *vide infra*.^{76a} One would expect that hydrogen bonding of the phenolic hydrogen would result in a stabilized reactant, and as a result, the rate constant of the simple HAT would be expected to decrease. These counterintuitive results can be rationalized on the basis of a faster HAT proceeding via SPLET as shown in Scheme 24 (see also **Antioxidants in Chemistry and Biology**).

Scheme 24 SPLET mechanism for phenol with a neutral radical.

The SPLET mechanism is shown in contrast to HAT for the reaction of phenol with a radical. SPLET is facilitated by the ionization of phenol followed by proton loss and then electron transfer to yield a phenoxyl radical and a neutral species. SPLET reactions proceed much faster than HAT when favorable, and are favored by solvents that promote ionization of the phenol as shown in Scheme 24.^{76c} In polar, hydrogen bond accepting solvents, reaction rates are faster as hydrogen bonding favors protonation of the solvent and simultaneous ionization of the phenol. Studies by Ingold consistently show no change in the ratio of rate constants for deprotonation by a given radical in two different solvents when comparing reactions involving several phenols and several radicals of varying reactivity.⁶⁹ This result provides further affirmation that the radical and its reactivity are not the limiting factor in SPLET mechanisms. In acidic media when SPLET is not favored (because ArOH remains protonated), PCET emerges in some cases as an alternative route to simple HAT.^{69e}

4.1.4 Proton-Coupled Electron Transfer

PCET is characterized by transfer of a proton coupled to the transfer of a nonbonded electron; it is important to note that for this mechanism, the proton and electron are transferred from different orbitals in a single step. PCET was first proposed by Mayer in theoretical investigation comparing the abstraction of hydrogen from toluene and phenol by their deprotonated radical counterparts and is shown in Scheme 25.⁷⁸

Studies of deprotonation by $\text{dpph}^\bullet$ from phenol displayed a much greater rate constant than the reaction with toluene.⁶⁹ The enhanced rate of

H-abstraction from phenol is because phenol has a nonbonding electron pair, and can react via PCET, while toluene does not and can only react via classical H-abstraction.⁶⁹ Interestingly, in nonpolar solvents reactions between $\text{dpph}^\bullet$ and phenols are believed to proceed through a product-like transition state and computations evidence the contribution of both HAT and PCET to the overall reaction mechanism.⁷⁹ For the reactions of $\text{dpph}^\bullet$ and *N,N*-dimethylanilines, a PCET mechanism is supported, rather than a sequential mechanism, by the observation of primary isotope effects.⁸⁰ During PCET, electron transfer occurs simultaneously with transfer of a proton between pairs of electrons on both reactants.⁷⁶ While both mechanisms involve the transfer of a proton and an electron, the difference between PCET and SPLET or ET/PT is that the first is concerted, while the last two are stepwise.⁶⁹ Mayer suggests that stepwise processes do not necessarily proceed through intermediates with a lower energy than that of concerted PCET. The increase in energy required to move both a proton and electron in concert (as opposed to just the electron as in an ET/PT) is often more than compensated for by the reduction in solvation energy displayed by the concerted process. In addition to the intrinsic barrier to reaction, the Gibbs free energy of PCET is consistently lower and the mechanism is thermodynamically favored over a stepwise process.⁸¹

4.1.5 Role of Hydrogen Bonding in Determining Mode of HAT

In the analysis of self decomposition reactions, phenol exhibited severely increased rates of reaction with the phenoxyl radical, relative to the carbon centered benzyl radical reaction with toluene. It has been suggested that the rate of hydrogen abstraction from phenol by phenoxyl radical was greater because hydrogen bonding between reactants created a short-lived intermediate complex.⁸² It should be noted that researchers suggest that hydrogen bonding between the two phenolic reactants does lend stability to the reactants and, in effect, decreases the reactivity of these species although this stabilization is offset by the closer proximity and enhanced accessibility of the two reacting species to each other.^{76,82} The increase in rate for the phenol reaction is attributed to the increased accessibility of the oxygen resulting from the smaller

Scheme 25 PCET mechanism for the reaction of a neutral radical with an alcohol. [Reprinted with permission from Ref. 63. Copyright 1991 American Chemical Society.]

radius of the oxygen in the phenol relative to the carbon being deprotonated on toluene.⁷⁶ In addition, Ingold highlights another well known consequence of a narrow reaction barrier, the increased probability of tunneling.^{69a} Proton tunneling in this case results from the closeness of the hydrogen bonded reacting molecules. The SPLET mechanism occurs so readily with phenols that, to observe the PCET pathway, ionization must be prevented by performing the reaction in the presence of acetic acid or another readily ionizable solvent. Favoring ionization of the solvent over the phenol disfavors the SPLET pathway (see also **Antioxidants in Chemistry and Biology**).⁷⁶

4.2 Radical Cation Deprotonations

4.2.1 Radical Cation Deprotonation: Thermodynamics

Radical cations, because of their electron deficient nature, are not likely to participate in HAT; instead, they undergo the analogous radical ion fragmentation, proton transfer. Factors that influence proton transfer are also significant for sequential HAT. In sequential HAT, radical ion intermediates undergo deprotonation as an elementary step of the overall HAT.

In deprotonations, in addition to the alkalinity of the base and strength of the breaking bond, the acidity of the radical is a factor that may significantly impact kinetics. Acidities for selected aromatic hydrocarbons, phenols, and amines are displayed in Table 9. The pK_a s estimated using thermodynamic cycles show solution phase acidity is drastically decreased relative to the gas phase acidity; ionization is less favored because energy is required to solvate solution phase ions.⁸³ Analogous results would be expected for all radical cations as a result of the increased electrophilicity of a cation relative to a neutral radical. A comparison of phenol in both DMSO and H₂O can be made; data suggests that in the less polar protic solvent the phenol is more acidic. These highly acidic compounds are known to react in HAT processes via either SPLET or PCET.

The predominate mechanism of HAT is largely dependent on reaction conditions and the ability of the phenol to ionize, as reflected by its pK_a . As radical cations are very acidic relative to their

neutral counterparts, electron transfer might be a good mechanism for catalysis especially when a C–H bond is broken during the reaction because a highly ionizable radical cation favors the subsequent deprotonation step. In Table 10, pK_a s calculated for several anilines and their corresponding radical cations are presented.

These compounds are of interest as a result of their structural similarity to several substrates for SET enzymes. In fact, until recently *N*-cyclopropyl-*N*-methylanilines were thought to be attractive mechanistic probes for mechanism of catalysis for these enzymes, vide supra. As expected, the radical cations are extremely acidic relative to the neutral bases. On average, for substituted anilines the radical cation is more than 20 orders of magnitude more acidic than the neutral counterpart! The large difference between the pK_a of the anilines and their radical cations

displays this increased acidity; analogous results would be expected for all radical cations as a result of the increased electrophilicity of a cation relative to a neutral radical. It is this increased acidity that puts forth PCET as a mechanism for catalysis involving these substrates in SET enzymes. The authors use this evidence to assert the idea that this decreased acidity decreases the possibility that HAT from the parent compound will proceed via a route involving deprotonation of a radical cation intermediate.⁶⁵ Notably, in the table above the acidity of the radical cation is increased relative to the neutral compound, although, the radical cations are not very acidic. Although values were not available for the pK_a s of the neutral dimethylanilines discussed below, these values are expected to exhibit alkalinity similar to that of other aromatic amines to a normal aliphatic C-H bond. In Table 10, pK_a values for several dimethylaniline radical cations are shown in CH_3CN and 0.5 M H_2O in CH_3CN . Table 10 presents the acidities of several dimethylaniline radical cations; the pK_a refers to the acidity of a C-H bond and not of a quaternary protonated amine; this point is further clarified by Scheme 24 showing the acid and its conjugate base. Moreover, the acidities of the aniline radical cations are greater than those of the corresponding dimethylaniline radical cations. From the values in Table 10, some general structure-acidity relationships are apparent. Values for pK_a s, calculated by Bordwell and Dinnocenzo, for both sets of compounds show similar trends, in that as the electron-donating ability of the substituent decreases, the pK_a increases, indicating the most electron-withdrawing para substituents are the most acidic. This result is cogent because as electron-donating ability decreases the positive charge localized on the nitrogen attached to (or adjacent to) the protic hydrogen in anilines (and dimethylanilines) also decreases. Again, as noted for the anilines, the dimethylaniline radical cations are not extremely acidic as might be expected. Although pK_a s were not provided for tertiary aliphatic amine radical cations, a study by Nelsen *et al.* states that several acidities calculated via a thermodynamic cycle show that the trialkyl amine radical cations exhibit average pK_a s of 15, suggesting tertiary alkyl amines radical cations are also not as acidic as might be expected.⁶⁵ These species do exhibit drastically lowered C-H bond dissociation energies in the radical cation, which

Table 11 pK_a s of some aliphatic amine radical cations.⁶⁵

Aliphatic amines	$pK_a^{*+} \text{H}_2\text{O}$

Pyrrolidine	5.5 ± 0.5

is attributed to orbital mixing between the C-H bond and the nitrogen's p orbital containing the unpaired electron.⁶⁵ The authors further note that the stability of the resultant carbon centered neutral radical is high due to resonance in support of the conclusion that acidity of the radical cation is not a primary factor in deprotonation. Griller noted in the study of deprotonation of alkyl radical cations by their parent compound that the amines were not basic enough to cause facile deprotonation to occur. Other studies of tertiary alkyl amine radical cations indicate stronger bases could significantly increase rates.⁸⁴ Nelsen poignantly asserts that a probable reason for this is that weaker bases do not deactivate the radical cation by deprotonation at a rate competitive with other means of decay.⁶⁵ In Table 11, strictly for comparison, the experimentally determined aqueous pK_a s of several secondary aliphatic amine radical cations are shown, displaying weakly acidic behavior, although more acidic than values calculated for their tertiary counterparts.

What is more, as the degree of substitution increases, the acidity of the amine decreases because alkyl substituents donate electron density to the nitrogen disfavoring deprotonation and a further increase in electron density on the nitrogen adjacent to the α carbon attached to the protic hydrogen.

4.2.2 Radical Cation Deprotonation: Kinetics

The kinetics of deprotonation of radical cations are dependent on several factors discussed above such as bond strength and pK_a of the radical cation; the strength of the base can also impact kinetics. For radical cations that have a low thermodynamic acidity, deprotonation may occur on a time scale slow enough that other routes of decay are plausible.^{65,85} Further convoluting kinetic analysis is difficulty distinguishing the rate constant

for radical cation deprotonation from that of other steps such as preceding electron transfer to generate the radical cation.⁶⁵ As dynamics of deprotonation has long been a topic of interest, there is a vast amount of literature pertaining to the topic.

Rate constants for deprotonation of dimethylaniline radical cations by acetate and pyridine have been determined previously by electrochemical and photochemical means.⁶⁴ Parker noted decay of the *N,N*-dimethylaniline radical cations by dimerization without base present, likewise noting this occurrence even for para substituted derivatives.^{64b} In the presence of base, facile deprotonation of these radical cations is observed and attributed to the positive charge on the nitrogen being relatively close to the α carbon deprotonated by the base.^{64b} Hammett and Bronsted analysis was performed for reactions with both bases. Hammett and Bronsted plots display linear free energy relationships of acidity of the radical cation with the nature of substituents, and base strength with rate constant for deprotonation.⁸⁶ The acetate deprotonation proceeds with a rate constant several orders of magnitude greater than that of the corresponding reaction with pyridine as shown in Table 12.^{64b}

Reactions of both bases with *para*-substituted *N,N*-dimethylanilines in acetonitrile show sensitivity to substituents effects giving linear Hammett

plots displaying the relationship between rate constant and $\sigma+$ yielding ρ values of 1.7 and 3.5 for acetate and pyridine, respectively.⁶⁴ Although these reactions are affected by the nature of the substituent, it should be noted that the magnitude of this effect decreases for the more energetically favorable, and consequently faster deprotonation by acetate. Bronsted analysis was also performed and α values were determined to be 0.24 and 0.51 for acetate and pyridine, respectively.^{64b} Because the α value is a measure of transition state location, a low value of α suggests an early transition state, consistent with acetate being more reactive.^{64b} Also, this explains the lower ρ value because acetate is more reactive; the rate is less sensitive to the nature of the substituent. Building on these observations and evidence from previous studies of radical cation kinetics, the authors suggest the mechanism for proton transfer shown in Scheme 26.

This mechanism is characterized by a fast reversible formation of an adduct followed by rate determining proton transfer as the complex breaks apart.^{63,64} Parker uses this mechanism to also account for observed experimental results for proton transfers involving several arene radical cations, and these studies provide further support for a mechanism involving adduct formation.^{63,87}

Later, photochemical analysis by Dinnocenzo of the acetate deprotonations of several substituted *N,N*-dimethylaniline radical cations revealed similar trends in rate constants for the *para* substituted compounds as previously noted by Parker although the magnitudes of the photochemically acquired rate constants were greater in all cases than those attained electrochemically. Differences are to be expected as ionic strength was maintained with different electrolytes and in the latter experiments a different solvent system was employed. The second-order rate constants for the reaction of several substituted dimethylaniline cations with acetate in 0.5 M H₂O in CH₃CN are shown in Table 13.^{64a}

Table 12 Rate constants of the reactions of *p*-substituted *N,N*-dimethylaniline radical cations with acetate and pyridine at 25 °C in CH₃CN with 0.5 M *n*-Bu₄CIO₄.

Substituent	k_{pyridine} (M ⁻¹ s ⁻¹)	k_{acetate} (M ⁻¹ s ⁻¹)
CH ₃ O	0.94	3.5×10^6
Cl	1.0×10^3	6.2×10^8
CN	2.5×10^5	1.0×10^9
NO ₂	1.4×10^5	3.0×10^9

Table 13 Rate constants for deprotonation of substituted *N,N*-dimethylaniline at room temperature in 0.5 M H₂O in CH₃CN with 0.5 M *n*-BuClO₄.⁶⁴

Substituent		<i>k</i> (M ⁻¹ s ⁻¹)
Para	OCH ₃	1.1 × 10 ⁷
	CH ₃	4.1 × 10 ⁷
	H	1.2 × 10 ⁸
	Cl	1.7 × 10 ⁸
	CF ₃	1.4 × 10 ⁸
Ortho	CH ₃	2.4 × 10 ⁸
	<i>t</i> -Bu	4.9 × 10 ⁹
	CH ₃ , CH ₃	3.6 × 10 ⁹

In the Dinnocenzo experiments, 0.5 M H₂O in acetonitrile in lieu of neat acetonitrile was the solvent used in an effort to maintain polarity as, in these studies, it was observed that the rate of deprotonation was significantly affected by ionic strength and polarity.^{64a} Small primary deuterium kinetic isotope effects were noted in kinetic studies of *N,N*-dimethylanilines with deuterated α carbons suggesting that the barrier to reaction is governed by the C–H bond breaking and an early transition state.^{64a} This corresponds well to the low α value observed by Parker, Bronsted relationship noted previously by Parker further confirming an early transition state. Dinnocenzo performed Bronsted analysis; an α value of 0.23 was observed, providing further support for the reactant like transition state.^{64a} In addition, the effect of electron-donating ability showed similar trends to those observed by Parker. Notably, the effect of ortho substituents is an increase in acidity of the amine.^{64a} This occurs for steric reasons as the nitrogen twists, consequently breaking up the conjugation with the aromatic ring, and concentrating electron density on the nitrogen as shown in Figure 15.^{64a}

This supposition was confirmed via density functional theory calculations that displayed a

**Figure 15** Ortho substituents increase amine acidity by twisting α -carbon out of the plane of the aromatic ring.

rotation of the nitrogen in the ortho substituted compounds.^{64a} Dinnocenzo further suggests this localization may lend an increased acidity to the analogous radical cation as charge and spin will also be localized in close proximity to the protic hydrogen supporting a more facile deprotonation.^{64a}

4.3 Comparing Mechanisms: HAT and Deprotonation

When proton and electron transfer occur in concert, whether it be involving a single hydrogen atom or a proton and an electron in a near by orbital, the reaction is typically more facile than a stepwise HAT because the solvation cost for involving deprotonation (and ions) outweighs the increase in reaction barrier for both processes to occur in a single step. Also, these processes have been shown to be more thermodynamically favorable than their sequential counterparts.⁸¹ The Evans–Polyani relationship is a great linear free energy relationship to describe simple concerted hydrogen transfer reactions; although many reactions, especially sequential HAT processes, are effected by complicating stereoelectronic or polar effects making this type of data treatment ineffective and necessitating investigation of kinetic dependence on other structural features such as thermodynamic acidity of the molecule undergoing HAT.

Generally, attempts to differentiate between deprotonation and HAT require careful and innovative experimental strategies. In sequential HAT mechanisms where deprotonation is the rate limiting step, it is impossible to elucidate the actual mechanism in some cases. In these cases, the elementary step with the greatest barrier is deprotonation. Therefore, factors governing deprotonation control the reaction, thereby making sequential HAT and deprotonation indistinguishable. This ambiguity is not limited to differentiating between sequential processes and deprotonation; concerted HAT and deprotonation can also be extremely difficult to discriminate as the transition states for a concerted HAT and deprotonation process are isoelectronic. Similar to the rearrangements discussed in the preceeding sections, the radical process (HAT) is intimately related to the radical ion process (deprotonation). In all cases transition state similarities predict similar kinetic trends and

often thermodynamic parameters that predict how specific structural features influence reactivity will trend similarly with kinetics for both the radical and radical ion processes. This is a lucky and important observation for many of us who study radical ion processes making assumptions that these charged species will behave similarly to their neutral analogs.

5 CONCLUSIONS

In the preceeding pages, a relatively comprehensive comparison of some radical and radical ion processes is presented. Two classes of radical reactions are discussed, rearrangements and atom transfers. In the context of atom transfer, routes leading to hydrogen transfer for neutral radicals are compared to the complementary radical ion process, deprotonation. Many sequential hydrogen transfer reactions involve deprotonation as an elementary step in their mechanism. What is more, concerted hydrogen transfer and deprotonation proceed through isoelectronic transition states, often leading to difficulties in discriminating the processes experimentally. Both classes of unimolecular rearrangements discussed, cyclopropyl ring openings and Δ -5-hexenyl cyclizations, have been utilized in synthesis and as radical clocks. Many trends observed for the well characterized Δ -5-hexenyl radical cyclizations extrapolate accurately to predicting the regio- and stereoselectivity of the lesser known radical anion siblings. Likewise, there is much to be gleaned about radical ion reactivity from the extensive work on cyclopropylcarbinyl $\rightarrow$ homoallyl rearrangements. The role of torsional strain, ring strain, and the stereo-electronic requirements for ring opening show both marked similarities as well as notable differences comparing the reactivity of radicals, radical anions, and radical cations of cyclopropyl substituted compounds. These particular reactions stand out from the others discussed because there is a rather complete data set for both radicals and radical anions. The cyclopropyl rearrangements provide an excellent example of how similar factors may influence radicals and their complimentary radical ions reactions while also clearly demonstrating the need for caution when extrapolating reactivity trends as the relative importance of factors influencing reactivity may change significantly with the introduction of charge. The similarities observed in the reactions

discussed herein are not fortuitous but rather indicative of similar activation or driving force trends for the complementary processes. Prudently used, these reactivity relationships are an excellent predictive tool when studying the radical ion analog of a previously characterized radical process.

1 INTRODUCTION

The atmosphere is a complex photochemical reactor. A vast majority of the chemical transformations that take place in the atmosphere involve reactions of free radicals that are generated by photodissociation of closed-shell precursors. The four chemical species N_2 , O_2 , H_2O , and Ar, account for more than 99.9% of the gas-phase molecules in the atmosphere.¹ We will see below that two of these major atmospheric components, namely, O_2 and H_2O , do play a significant role in atmospheric chemistry. However, a vast majority of the gas-phase chemistry of interest for understanding major environmental issues such as climate change, urban air quality, stratospheric ozone depletion, as well as the ability of the atmosphere to cleanse itself of pollutants, is driven by reactions of trace components that have mixing ratios (i.e., mole fractions) ranging from less than 1 part per trillion up to a few parts per million.

Because the atmosphere is an oxidizing environment, atmospheric chemistry can be viewed as low-temperature combustion. However, the radical chain reactions that ultimately produce oxidized species such as CO_2 occur rather slowly under atmospheric conditions. Biological processes contribute to fairly rapid rates of injection of chemically reduced species such as methane (CH_4) into the atmosphere, and such species are present at much higher levels than chemical equilibrium considerations would suggest. For example, the atmospheric mixing ratio of CH_4 , which is 1.7 ppmv

(parts per million by volume), is more than 100 orders of magnitude greater than would be expected if the combustion reactants and products CH_4 , O_2 , H_2O , and CO_2 were present at equilibrium concentrations. As a result, a description of the chemistry of the atmosphere requires the application of chemical kinetics. Rate coefficients for a multitude of free-radical reactions are necessary input parameters into photochemical models that are used to interpret field observations and make predictions about the future state of the atmosphere. Both NASA (National Aeronautics and Space Administration) and IUPAC (International Union of Pure and Applied Chemistry) sponsor panels that critically review the literature and recommend kinetic parameters for use in modeling atmospheric chemistry. The most recent comprehensive NASA panel evaluation appeared in 2006,² with an updated version scheduled to appear in early 2011;³ the NASA evaluations appear as Jet Propulsion Laboratory (JPL) publications and are available to the public on a dedicated web site.^{2,3} The most up-to-date IUPAC evaluations have been published as a series of papers in the journal *Atmospheric Chemistry and Physics* that have appeared over the 2004–2010 time period.^{4–8} Data sheets for individual reactions are also available at www.iupac-kinetics.ch.cam.ac.uk.

1.1 The Atmospheric Condensed Phase

Condensed-phase processes play a significant role in atmospheric chemistry. At any instant in time, clouds are found above approximately 60% of the

This article was corrected on 23-July-2012

earth's surface.⁹ The liquid water content of clouds is typically in the range 0.1–0.3 g of H₂O per cubic meter, which corresponds to a volume mixing ratio of liquid water (volume of H₂O(l)/volume of air) in the range $(1-3) \times 10^{-7}$.⁹ Many atmospheric trace gases are highly soluble in water and such species can be taken up into cloud water and undergo chemical transformation in the aqueous phase. Uptake into cloud water and subsequent removal from the atmosphere by rain is an important pathway for removing some soluble pollutants from the atmosphere. However, most clouds evaporate rather than produce rain. When a cloud evaporates, some chemical substances are returned to the gas phase but often in a chemically more oxidized form than upon initial uptake into the aqueous phase. Since oxidized substances are typically less volatile than their reduced precursors, cloud evaporation often does not result in complete return to the gas phase of all mass that entered the droplet by uptake from the gas phase: that is, “cloud processing” of atmospheric particles (see below) represents a mechanism for particle growth.

In addition to cloud droplets, particles represent another form of condensed-phase material in the atmosphere. There is currently enormous interest in anthropogenic (i.e., resulting from human activity) atmospheric particles because of their health effects and their climate impacts, which result from their role in scattering and absorbing atmospheric radiation (direct effect) as well as their role in altering cloud properties (indirect effect).^{1,9,10} It is worth pointing out that cloud droplets cannot form by condensation of pure water vapor, but instead must grow from particles that have the correct thermodynamic properties to act as cloud condensation nuclei.⁹ In addition to their importance in health effects and climate, particles provide a medium on (or in) which some chemical transformations can occur that would not occur in the gas phase. One important example of this behavior that will be discussed in a later section of this article is the role of polar stratospheric cloud (PSC) particles in creation of the Antarctic ozone hole.

1.2 Vertical Layers in the Atmosphere

Approximately 99.9% of the mass of the atmosphere is contained in the lowest 50 km of altitude and

this altitude regime is divided into two distinct layers, the troposphere and the stratosphere.^{1,9–11} This article will focus on radical chemistry in these layers. Some of the basic characteristics of the troposphere and stratosphere are summarized below. References for individual statements are not given since the characteristics summarized below are discussed in atmospheric chemistry textbooks.^{1,9–11}

The troposphere is the lowest layer of the atmosphere. It extends from the earth's surface to an altitude that varies from about 8 km at polar latitudes to about 15 km in the tropics. Approximately 85% of the atmospheric mass is contained in the troposphere. The primary energy source in the troposphere is radiative heating from the earth's surface. As a result, temperature drops with increasing altitude, and rapid vertical mixing by convection can occur. Solar radiation at wavelengths shorter than 290 nm is absorbed at altitudes above the top of the tropopause (the boundary between the troposphere and stratosphere), so all photochemistry in the troposphere is initiated by photons with $\lambda > 290$ nm. The average temperature at the earth's surface is currently estimated to be 288 K, while the average temperature at the tropopause is approximately 210 K. The troposphere can be further divided into two vertical layers, the planetary boundary layer and the free troposphere. The planetary boundary layer tops out during daytime hours at altitudes that vary from about 1–3 km depending on the amount of solar heating of the surface. After sunset, the surface cools radiatively more rapidly than the overlying atmosphere, leading to the creation of a temperature inversion and a low boundary layer top at night. Pollutants emitted into the boundary layer at the surface are mixed into the free troposphere on a timescale of a day or two, and vertical mixing to the tropopause occurs, on average, on a timescale of 1 month. In strong thunderstorms, chemical species can be transported from the boundary layer top to the tropopause in only a few hours. The general circulation pattern in the troposphere is such that nonreactive chemical species that are emitted into the atmosphere at mid-latitudes in the Northern Hemisphere are transported to the tropics or to polar latitudes on a timescale of 1–2 months and to the Southern Hemisphere on a timescale of about 1 year. The competition between transport and chemical loss results in a strong correlation between a pollutant chemical's lifetime and its distribution in the troposphere; less reactive species tend to be uniformly distributed,

whereas more reactive species tend to be found only in the vicinity of sources.

The stratosphere extends from the tropopause to an altitude of approximately 50 km. The primary energy source in the stratosphere is absorption of solar radiation by O_2 and O_3 ; ozone (O_3) is produced by the association reaction of atomic oxygen, which is the product of O_2 photodissociation, with O_2 . In the stratosphere, temperature increases with increasing altitude from about 210 K at the tropopause to about 270 K at the stratopause (the boundary between the stratosphere and the overlying mesosphere). Approximately 90% of atmospheric ozone (O_3) resides in the stratosphere, and this ozone, in combination with O_2 , prevents radiation at wavelengths shorter than 290 nm from penetrating to the earth's surface where it would have harmful effects on the biosphere. Hence, the focus in stratospheric chemistry is on understanding how anthropogenic activity impacts the ozone levels. Because temperature increases with increasing altitude, the stratosphere is very stable toward vertical mixing. Furthermore, the tropopause defines the location of a substantial meteorological barrier to vertical transport. The characteristic time for transport from the troposphere to the stratosphere is estimated to be 7.4 years. Hence, only reasonably long-lived tropospheric species have a significant probability of being transported to the stratosphere. For this reason, the chemistry of the stratosphere is much simpler than that of the troposphere. Atmospheric pressure in the stratosphere varies from about 100 Torr at the tropopause to about 0.1 Torr at the stratopause. The lower pressure in the stratosphere compared to the troposphere results in much more varied chemistry for atomic oxygen in the stratosphere than in the troposphere, where essentially every ground-state oxygen atom produced combines with O_2 to generate O_3 . We will see in Section 2 on stratospheric radical chemistry that atomic oxygen plays a central role in a number of catalytic cycles that can destroy ozone.

1.3 Radical Families in Atmospheric Chemistry

In our discussion of atmospheric radical chemistry, it will be useful to define families of reactive species (all but one of which are radicals). The families of primary interest are $O_x \equiv O + O_3$,

$NO_x \equiv NO + NO_2$, $HO_x \equiv OH + HO_2$, $ClO_x \equiv Cl + ClO$, and $BrO_x \equiv Br + BrO$. Later in this article, we will sometimes write HO_2 (hydroperoxyl radical) as HOO. The NO_3 radical is sometimes included in the NO_x family, and the H atom is sometimes included in the HO_x family. We will also have occasion to discuss the chemistry of I atoms and IO radicals, which together make up the IO_x family. The usefulness of defining radical families is based on the fact that, in the atmosphere, the family members are interconverted much more rapidly than the family is either produced or destroyed. Hence, steady-state kinetics can often be employed to evaluate concentration ratios of family members under conditions where it is inappropriate to invoke steady-state kinetics to evaluate the total concentration of all family members.

Except where necessary for clarity, in the text we write chemical formulae for radicals without using dots to designate the site of the unpaired electron. The notation we use is that customarily employed in the atmospheric chemistry literature. As a helpful guide to nonexperts, we include dots in the figures, where most of the common atmospheric radicals appear. No dot appears on the NO_3 radical in Figure 2 because the three oxygen atoms share the unpaired electron density.

1.4 Rates of Photochemical Reactions in the Atmosphere

In atmospheric chemistry models, it is often necessary to evaluate the rate of occurrence of a photochemical reaction. For this purpose, a first-order photochemical rate coefficient (often referred to as a J -value in the atmospheric chemistry literature) can be defined as follows:¹

$$J_X = \int \sigma_X(\lambda) \Phi_X(\lambda) I(\lambda) d\lambda$$

In the above equation, J_X is the first-order rate coefficient for photochemical destruction of X, $\sigma_X(\lambda)$ is the wavelength-dependent cross section for X, $\Phi_X(\lambda)$ is the wavelength-dependent quantum yield for photochemical destruction of X, and $I(\lambda)$ is the actinic flux distribution function which represents a measure of the number of photons of wavelength between λ and $\lambda + d\lambda$ crossing a unit horizontal surface from any direction per unit time.

The J -values can sometimes not only be determined from *in situ* atmospheric measurements, but can also be calculated using the evaluated absorption cross sections and quantum yields^{2–8} in conjunction with tabulated actinic flux distributions.¹⁰ By choosing the appropriate values for $\Phi_X(\lambda)$, one can define a J -value for photochemical destruction of X, photo-excitation of X, or production of a particular photoproduct from X.

2 RADICAL CHEMISTRY IN THE STRATOSPHERE

In the late 1800s, Hartley identified ozone as the chemical species responsible for the 290-nm cut-off of solar radiation penetrating into the lower atmosphere¹²; hence, the strong ozone absorption feature centered at $\lambda \sim 255$ nm is known as the *Hartley band*. The first accurate spectroscopic measurement of the ground-level ozone mixing ratio was reported by Strutt in 1918,¹³ and reliable measurements of the ozone column, that is, the total number of ozone molecules in a column of unit cross-sectional area extending from ground level to the top of the atmosphere, became available during the 1920s.^{14,15} The combined results of the ground-level ozone measurements and the ozone column measurements implied that there must be an altitude regime where ozone mixing ratios are significantly higher than they are at the earth's surface. A photochemical model capable of predicting the presence of an "ozone layer" was proposed by Chapman in 1928.¹⁶

In this section on stratospheric radical chemistry, we will first describe the mechanism proposed by Chapman and compare its predictions with observations. We will find that the observed ozone levels can be accounted for only if radical-catalyzed destruction of odd-oxygen is incorporated into the overall chemical mechanism. Details of the radical-catalyzed odd-oxygen destruction chemistry are discussed. The Antarctic ozone hole was discovered during the 1980s,¹⁷ which stimulated field and laboratory work that led to the realization that heterogeneous (i.e., multiphase) chemistry plays an important role in controlling stratospheric ozone levels.¹⁸ New radical chemistry that is driven by the occurrence of heterogeneous reactions is described.

2.1 The Chapman Mechanism

The photochemical mechanism proposed by Chapman contained five elementary steps; one of these steps, that is, the recombination of two oxygen atoms to form O₂, is now known to be unimportant under stratospheric conditions. The four reactions that have stood the test of time are the following:

The species M in reaction (2) is any third body collision partner; in the atmosphere, M is mostly N₂ and O₂. Under stratospheric conditions, reactions (2) and (3), which are the reactions that interconvert the members of the O_x family, occur much more rapidly than reactions (1) and (4), which are the reactions that produce and destroy odd-oxygen (O_x). Reaction (2) is found to be in its low-pressure termolecular limit under all conditions that exist in the atmosphere,² so its rate is proportional to P^2 (P = pressure). Since pressure decreases approximately exponentially with altitude,¹ the rate of reaction (2) falls off dramatically with increasing altitude. On the other hand, the rate of reaction (3) increases with increasing altitude because the ultraviolet radiation that is most effective at photolyzing O₃ is attenuated via O₃ absorption as it passes downward through the stratosphere. It is clear that, on the basis of the above considerations, the Chapman mechanism predicts that the ratio [O]/[O₃] should increase dramatically as a function of altitude and this is, indeed, observed to be the case.^{1,11} A quantitative kinetic analysis of the Chapman mechanism under low latitude conditions that uses up-to-date values for J_1 , k_2 , J_3 , and k_4 yields a [O₃] versus altitude dependence that reproduces the observed dependence reasonably well; the altitude of maximum [O₃] is predicted to be ~ 28 km by the kinetic analysis and is observed to be ~ 24 km.¹

It is worth pointing out that photodissociation of O₂ and O₃ produces both ground-state ³P and electronically excited ¹D oxygen atoms. Electronically excited oxygen atoms are much more reactive than ground-state oxygen atoms and, as we will discuss later in this article, O(¹D) plays a crucial role

in the production of atmospheric HO_x , NO_x , and ClO_x radicals; it is also an important initiator of the degradation of numerous long-lived atmospheric constituents. However, under stratospheric conditions, a vast majority of $\text{O}(^1\text{D})$ atoms are deactivated to $\text{O}(^3\text{P})$ via quenching by N_2 and O_2 . Hence, for purposes of analyzing the Chapman mechanism, it is not necessary to distinguish between the two types of oxygen atoms.

It took nearly 50 years following the publication of the Chapman mechanism before the rate coefficient k_4 was quantified over the stratospheric temperature regime.^{19–22} Once k_4 was known quantitatively, it became possible to compare the observed ozone concentrations with those predicted on the basis of the Chapman mechanism and also to compare the O_x production rate from (1) with the O_x loss rate from (4); since globally averaged stratospheric O_3 levels are not changing significantly as a function of time, the overall production and loss rates of O_x must be approximately equal. Odd-oxygen concentrations predicted from a steady-state analysis based on the Chapman mechanism are larger than the observed concentrations by more than a factor of two.¹ Furthermore, a careful analysis of odd-oxygen chemical production, chemical loss, and transport rates shows that loss of O_x via the combination of (4) and downward transport to the troposphere occurs at a rate that is only about 20% of the production rate from (1).²³ The implication of the above findings

is that there must be additional chemical sinks for stratospheric odd-oxygen. Furthermore, since stratospheric odd-oxygen is present in large excess over any species that could destroy it via chemical reaction, it appears that the additional chemical sinks must be *catalytic* in nature. We examine pathways for radical-catalyzed destruction of stratospheric odd-oxygen in the next section.

2.2 Radical Catalysis of Odd-Oxygen Destruction

Bates and Nicolet suggested that HO_x radicals can catalyze stratospheric odd-oxygen destruction in 1950, more than 20 years before it was firmly established that catalytic pathways must be important.²⁴ During the early 1970s, a number of benchmark papers appeared showing that NO_x ,^{25–29} ClO_x ,^{29–32} and BrO_x ³³ radicals were also likely to be important catalysts for odd-oxygen destruction. The early work of Crutzen, Molina, and Rowland was influential in the award of the 1995 Nobel Prize in Chemistry to these three atmospheric chemists.^{25,26,31}

Key chemical pathways in the gas-phase stratospheric chemistry of HO_x , NO_x , ClO_x , and BrO_x radicals are summarized in Figures 1–4. The figures show significant radical source reactions, significant catalytic cycles, significant null cycles, and the key reactions governing the formation and destruction of

Figure 1 Schematic overview of the gas-phase stratospheric chemistry of HO_x radicals ($X=\text{Cl}, \text{Br}$). [Adapted (with modifications) from Ref. 158.]

Figure 2 Schematic overview of the gas-phase stratospheric chemistry of NO_x radicals ($X = \text{Cl}, \text{Br}$). [Adapted (with modifications) from Ref. 158.]

Figure 3 Schematic overview of the gas-phase stratospheric chemistry of ClO_x radicals. [Adapted (with modifications) from Ref. 158.]

reservoir species. The figures are coded with source compounds shown in rectangular boxes, reactive radicals shown in circular boxes, reservoir species shown in elliptical boxes, and one gas-phase sink species (H_2O , a sink for HO_x radicals) shown in a triangular box. Catalytic cycles are discussed in detail in this section. Null cycles and the chemistry of reservoir species are discussed in the next section.

To complete a catalytic cycle, member 1 of a radical family must be converted to member 2 via a reaction that destroys ozone, and member 2 must be cycled back to member 1 without re-forming ozone. The net reaction of the cycle

must be the conversion of odd-oxygen to O_2 . Under stratospheric conditions, the net reactions for the most important catalytic cycles are either reaction (4) or (5):

It is worth noting that, while the uncatalyzed $\text{O} + \text{O}_3$ reaction (4) occurs at a significant rate in the stratosphere, the uncatalyzed $\text{O}_3 + \text{O}_3$ reaction (5) is negligibly slow. As discussed in Section 2.1, the ratio $[\text{O}]/[\text{O}_3]$ increases dramatically with increasing altitude. As a result, catalytic cycles where the net is (4) tend to be most important in the middle and upper stratosphere whereas those where the net is (5) tend to be most important in the lower stratosphere.

Numerous catalytic cycles can be identified upon examination of Figures 1–4. Those that are thought to be most important in controlling stratospheric ozone levels are written out below. Each elementary step is shown, and the step that is rate-limiting under typical stratospheric conditions is written in ***bold italics***. In the atmospheric chemistry literature, it is customary to identify a cycle by specifying the reactants in the rate-limiting step. For example, the first catalytic cycle shown below is often referred to as the $\text{O} + \text{HO}_2$ cycle; we will use this approach to identify cycles. Note that in Figures 1–4 and in the reactions written out below, $\text{O} \equiv \text{O}(^3\text{P})$, the ground state oxygen atom.

Figure 4 Schematic overview of the gas-phase stratospheric chemistry of BrO_x radicals.

By the early 1980s, laboratory studies of key reactions (see above) in combination with results from field observations of the O_3 column made it possible to assess the potential for observed stratospheric ozone levels to be accounted for by including catalytic pathways for ozone destruction along with Chapman chemistry in model simulations.³⁴ It was concluded that the observed ozone columns could readily be accounted for by incorporating HO_x catalysis, NO_x catalysis, or ClO_x catalysis either separately or in combination. However, the effects of the different radical families were found to be nonadditive, with the nonlinear behavior appearing to result primarily from the coupling between NO_x chemistry and the chemistries of other families. As we discuss in the next section, the presence of NO_x radicals reduces the efficiency with which other radical families can destroy ozone because NO_x participates in null cycles that compete with catalytic cycles, and because NO_x participates in the formation of reservoir species that tie up HO_x , ClO_x , and (to a lesser extent) BrO_x radicals in relatively unreactive forms, thus inhibiting their ability to destroy ozone.

2.3 Null Cycles and Reservoir Formation

To complete a null cycle, member 1 of a radical family must be converted to member 2 via a reaction that destroys ozone, and member 2 must be cycled

back to member 1 via a pathway that re-forms ozone. The net reaction of the cycle must be no change. Important null cycles are written out below with each elementary step shown.

Net: Nothing

Net: Nothing

Net: Nothing

Net: Nothing

Net: Nothing

Null cycles compete with catalytic cycles, thereby reducing the rate of catalytic ozone loss. Model calculations that evaluate stratospheric ozone levels are very sensitive to the choice of rate coefficients for reactions (22) and (24), even though the primary role of these reactions is their involvement in “net nothing” cycles.

Another group of gas-phase reactions that impact stratospheric ozone levels are reactions that interconvert radicals and reservoirs. A reservoir species is one that serves as a holding tank for reactive radicals, tying them up in a less reactive form. We distinguish *reservoirs* from *sinks* by their ultimate fate. Reservoirs are converted back to reactive radicals, whereas sink species are lost from the stratosphere without being converted back to reactive radicals. The partitioning of reactive species between radicals and reservoirs strongly influences the effectiveness of a radical family as a catalyst for ozone destruction. All species shown in elliptical boxes in Figures 1–4 are reservoir species; the key reactions that convert radicals to reservoirs and reservoirs back to radicals are shown in these figures.

Three of the five null cycles specified above involve the interaction of NO_x radicals with other radical families. In addition, formation of the key reservoir species nitric acid (HNO_3 or HONO_2), peroxyxynitric acid (HNO_4 , HO_2NO_2 , or HOONO_2), chlorine nitrate (ClNO_3 or ClONO_2), and bromine nitrate (BrNO_3 or BrONO_2) also involve interaction of NO_x radicals with other radical families. The effect of the occurrence of both the family-coupling null cycles and the family-coupling reservoir reactions is reduction in the effectiveness of XO_x ($\text{X}=\text{H}$, Cl , or Br) as a catalyst for ozone destruction. For this reason, the dependence of the overall ozone removal rate on $[\text{NO}_x]$ is highly nonlinear over the range of $[\text{NO}_x]$ that can be present in the stratosphere. When NO_x levels are low, the ozone removal rate decreases with increasing $[\text{NO}_x]$ because of the effect of increasing NO_x on HO_x , ClO_x , and BrO_x catalysis. However, when NO_x levels get high enough, the $\text{O} + \text{NO}_2$ catalytic cycle becomes the dominant mechanism for ozone destruction and the ozone removal rate increases with increasing NO_x .³⁵

2.4 Effectiveness of FO_x , ClO_x , BrO_x , and IO_x as Catalysts for Ozone Destruction

The halogen radical families ClO_x and BrO_x have played a prominent role in our discussion of gas-phase stratospheric radical chemistry, whereas the radical families FO_x and IO_x have not. It is interesting at this point to examine the differences between the gas-phase chemistries of the different halogen radicals.

The production rate of F atoms in the stratosphere is rather low because only very high energy radiation is capable of releasing F atoms from organic fluorine compounds via photolysis. Furthermore, a significant fraction of the F atoms that are formed react by abstracting hydrogen from CH₄ or H₂O to produce HF. Unlike other HX species (X = Cl, Br, I), HF does not react with OH to re-form the F atom. Hence, HF is not a reservoir species; it is a sink species. For this reason, FO_x radicals are of negligible importance as a catalyst for ozone destruction.

The production rate of ClO_x radicals via photodissociation of chlorofluorocarbons (CFCs) and hydrochlorofluorocarbons (HCFCs), reactions of CFCs and HCFCs with O(¹D), and reactions of HCFCs with OH is significant. Once formed, ClO_x radicals are converted to reservoir species efficiently. The most important reservoir-forming reactions are the following:

Under conditions where gas-phase chemistry is dominant, the partitioning of reactive chlorine at steady state is typically about 10% ClO_x radicals and 90% reservoirs in the upper stratosphere and about 2–3% ClO_x radicals and 97–98% reservoirs in the lower stratosphere.¹⁸ We will see in the next section that heterogeneous (i.e., multiphase) chemistry can change the picture significantly. However, in parts of the stratosphere that are not heavily impacted by heterogeneous chemistry, chlorine is only moderately effective as a catalyst for ozone destruction because its partitioning is primarily to reservoirs.

Because absorption spectra of organic bromine compounds are red-shifted from those of the analogous organic chlorine compounds, the bromine source compounds CH₃Br, CF₃Br, and CF₂ClBr release Br atoms by photodissociation very efficiently in the lower stratosphere where O₃ levels are high. Formation of the HBr reservoir does not occur nearly as rapidly as the formation of the HCl reservoir because reactions of Br with CH₄ and H₂ are endothermic and do not occur at significant rates in the stratosphere. Furthermore, the rate coefficient for the OH + HBr reaction, which converts HBr to Br, is considerably larger than that for the OH + HCl reaction, which converts HCl to Cl (a factor of 14 at 300 K, increasing to a factor of

33 at 200 K).² Hence, while HCl is a key reservoir for ClO_x radicals, HBr is of only minor importance as a reservoir for BrO_x radicals. The rates of formation of the XONO₂ reservoir species (X=Cl, Br) are very similar, but the rate of conversion of BrONO₂ to BrO_x by photolysis is significantly higher than that of ClONO₂ to ClO_x by photolysis (again because the BrONO₂ absorption spectrum is red-shifted relative to the ClONO₂ absorption spectrum).² In regions of the lower stratosphere not heavily impacted by heterogeneous chemistry, differences in the rates of formation and loss of key reservoirs result in a much higher fraction of reactive bromine (about 50%) being present as radicals compared to the fraction of reactive chlorine present as radicals (2–3%, see above). As a result, bromine is much more effective than chlorine *on a per atom basis* as a catalyst for the destruction of stratospheric ozone. However, the total chlorine levels in the stratosphere are currently a factor of 160 larger than total bromine levels, so chlorine contributes more than bromine to ozone depletion.³⁶

If iodine were present at significant levels in the stratosphere, it would be a potent catalyst for ozone destruction because reactive iodine would be partitioned almost entirely into IO_x radicals. However, the absorption spectra of organic iodine source compounds are sufficiently red-shifted compared to those of the analogous bromine and chlorine compounds, so that the iodine compounds photodissociate efficiently in the troposphere; their tropospheric lifetimes are typically a few days. Hence, the iodine source compounds do not reach the stratosphere in significant quantity and iodine is thought to be unimportant as a catalyst for stratospheric ozone destruction.

2.5 Role of Heterogeneous Chemistry in Stratospheric Ozone Depletion

The first paper reporting the observation of the Antarctic ozone hole appeared in 1985.¹⁷ Measurements of ozone vertical profiles at the South Pole during the late 1980s and early 1990s showed that ozone mixing ratios were typically normal in late August, showing peak O₃ partial pressures of about 15 mPa at altitudes between 15 and 20 km.¹ However, by mid-October, O₃ levels over the South Pole at altitudes of 10–20 km dropped to near zero.¹ Examination of the time series of observed

average October O₃ vertical profiles at the South Pole showed that the massive depletion of O₃ at lower stratospheric altitudes was not observed in the late 1960s, but evolved over a 15-year period between 1970 and 1985.^{18,37}

The typical air circulation pattern that exists in the wintertime Antarctic lower stratosphere is such that the polar air mass is isolated; that is, it mixes only very slowly with air from lower latitudes.¹ Hence, any chemical changes that occur in this isolated “polar vortex” are not diluted. In addition, temperatures are so low (~190 K) that PSC particles, which are composed of water, nitric acid, and sulfuric acid, form.^{1,18}

During the late 1980s, large field programs were organized to develop an understanding of the Antarctic ozone hole. The key data that helped to establish the cause of the ozone hole involved observations of reactive chlorine species, most notably ClO.^{38–40} Inside the lower stratosphere polar vortex, springtime ClO mixing ratios were found to reach 1 ppbv (parts per billion by volume), more than 100 times greater than the mixing ratio predicted by photochemical models employing only gas-phase chemistry (Sections 2.1–2.4 above).^{18,38–40} A possible mechanism for generation of large levels of ClO involves production of ClO_x photolytic precursors via reactions on (or in) PSC particles, and laboratory studies carried out during the late 1980s and early 1990s demonstrated the occurrence at atmospherically relevant rates of a number of such *heterogeneous* reactions:^{18,41–52}

The homogeneous gas-phase versions of reactions (29)–(35) are all extremely slow and do not play a significant role in atmospheric chemistry. The above

heterogeneous reactions convert ClO_x and BrO_x reservoirs to photochemically labile Cl₂ and BrCl which are released to the gas phase and build up in concentration during the long, dark polar winter. When the sun comes up in the polar spring, Cl₂ and BrCl are rapidly photolyzed to produce large quantities of ClO_x and BrO_x radicals. Furthermore, NO_x radicals are depleted from the gas phase because the HNO₃ that participates in PSC formation as well as the HNO₃ product of reactions (29)–(31), (33), and (34) largely remains in the condensed phase as NO₃[−]. Hence, the rates of null cycles and reservoir-forming reactions of NO_x are very slow, and ClO_x radical mixing ratios reach extremely high levels; levels of BrO_x radicals are also somewhat higher than under “unperturbed” stratospheric conditions. Under Antarctic lower stratosphere springtime conditions, the ClOOCl + *hν* catalytic cycle, that is, reactions (11), (18), and (19), which is unimportant in the unperturbed stratosphere, becomes dominant. The ClOOCl + *hν* cycle accounts for about 80% of odd-oxygen destruction under ozone hole conditions, with most of the remaining 20% attributable to the ClO + BrO cycle, that is, reactions (11), (14), and (20).^{1,18}

The ClO dimer, which is formed via the ClO + ClO association reaction (18), is a key intermediate in polar stratospheric chemistry. The most stable isomer of Cl₂O₂ is thought to be ClClO₂.⁵³ However, the dominant product of the ClO self-reaction has been shown to be ClOOCl,⁵⁴ and this isomer is thought to be the only one of importance in atmospheric chemistry. The strength of the ClO–OCl bond is only 76 ± 3 kJ mol^{−1},^{2,53} so ClOOCl is thermally stable only at the low temperatures typical of the polar vortex. If ClOOCl photodissociated via rupture of the weak O–O bond, then its formation and photolysis would complete a null cycle and ozone loss would not occur. However, careful laboratory studies have shown that the dominant photodissociation channel produces Cl + ClOO, although small yields of ClO are observed at λ > 300 nm.^{55–59} The Cl–OO bond is so weak (~20 kJ mol^{−1}) that this species fragments almost instantaneously to Cl + O₂.^{3,60}

Because reaction (19) is the rate-limiting step in the catalytic cycle that dominates springtime polar ozone destruction, it is not surprising to find that model simulations identify uncertainty in the rate of this reaction, which arises primarily from uncertainties in ClOOCl absorption cross sections

at $300\text{ nm} < \lambda < 450\text{ nm}$ (the important wavelength range for atmospheric photolysis), as the single largest chemical uncertainty limiting quantitative modeling of polar ozone depletion.⁶¹ The relevant cross sections are difficult to measure because they are relatively small (particularly at $\lambda > 350\text{ nm}$) and because it is difficult to prepare ClOOCl samples that are free of absorbing impurities. The absorption cross sections recommended in the 2006 NASA panel evaluation² represent an average of results from two studies that lead to photodissociation rate coefficients (i.e., J -values) that differ by a factor of 2.6.^{62,63} The largest set of measured cross sections⁶² appear to be the most consistent with ClO and ClOOCl levels observed in field studies.⁶⁴ In 2007, Pope *et al.* published a careful experimental study where a novel approach to minimize interferences from impurity absorptions was employed;⁶⁵ the results of this study suggest that the ClOOCl photolysis rate is a factor of 6.2 slower than the 2006 NASA panel recommendation and about an order of magnitude too slow to be consistent with field observations assuming that the chemical mechanism used to interpret the field observations is correct. The Pope *et al.* paper has stimulated significant recent work on the ClOOCl absorption spectrum in a number of leading laboratories around the world.^{59,66–71} It now appears that the majority of new laboratory results predict a relatively large photolysis rate coefficient that is consistent with field observations as interpreted using presently understood chemistry. In their study, Pope *et al.* assumed that a long-wavelength feature in the measured absorption spectrum resulted from Cl₂ impurity and used the known wavelength dependence of the Cl₂ absorption spectrum in conjunction with a least squares fitting procedure to correct the spectrum. Results presented by von Hobe *et al.*⁶⁷ suggest that the long-wavelength spectral feature observed by Pope *et al.* is actually a weak ClOOCl band, so Pope *et al.* probably overcorrected for impurity absorption.

The research conducted to understand the Antarctic ozone hole demonstrated the importance of heterogeneous chemistry involving PSCs. The lower stratosphere contains large amounts of sulfate aerosol over wide regions of latitude,⁷² and the potential role of heterogeneous chemistry at mid-latitudes was investigated extensively during the late 1980s and in the 1990s. An excellent review of our understanding is presented by Solomon.¹⁸

While many of the heterogeneous reactions (29)–(35) appear to play a role in mid-latitude stratospheric chemistry, perhaps the single most important reaction is N₂O₅ hydrolysis (reaction 30); this reaction causes significant reduction in NO_x levels in the lower stratosphere, thereby reducing the importance of the O + NO₂ catalytic cycle and, by reducing competition from null cycles and also reducing the formation rate of NO_x-containing reservoirs, increasing the efficiency of HO_x, ClO_x, and BrO_x catalytic cycles. McElroy *et al.* have modeled lower stratosphere mid-latitude chemistry using (i) a gas-phase-only chemical mechanism and (ii) the same gas-phase mechanism with N₂O₅ hydrolysis in aerosol particles added.⁷³ The gas-phase-only model predicts that the O + NO₂ catalytic cycle dominates ozone destruction at all altitudes between 18 and 30 km, accounting for about 70% of ozone loss independent of altitude. When N₂O₅ hydrolysis is added to the model, the fraction of ozone loss attributable to the O + NO₂ catalytic cycle drops from about 70% at 30 km to about 13% at 18 km and the HO₂ + O₃ catalytic cycle becomes the single most important ozone loss process at altitudes below 23 km, accounting for about 75% of ozone loss at 18 km.⁷³ Model calculations by Lary,⁷⁴ which employ a more complete chemical mechanism than the one employed by McElroy *et al.*, also suggest the importance of the HO₂ + O₃ catalytic cycle in the lower stratosphere, as does data from the SPADE (Stratospheric Photochemistry, Aerosols, and Dynamics Expedition) field campaign where a complete suite of key radical intermediates was measured.³⁵

3 RADICAL CHEMISTRY IN THE TROPOSPHERE

Understanding radical chemistry in the troposphere is crucial for developing a predictive understanding of key societal issues including the ability of the atmosphere to cleanse itself of pollutants, urban air quality, and climate change. Tropospheric radical chemistry also affects stratospheric ozone because the amounts of many ClO_x and BrO_x source compounds that reach the stratosphere are limited by their rates of destruction in the troposphere. Whereas all stratospheric chemistry can be understood in terms of a few hundred elementary

reactions, tropospheric chemistry is much more complex, primarily because of the presence in the troposphere of an enormous variety of organic compounds, most of which are too short-lived to be transported to the stratosphere. As a result, understanding all of tropospheric radical chemistry at the elementary reaction level represents a goal that is virtually impossible to achieve.

In this section, we focus first on a discussion of the key species that initiate the atmospheric degradation of organic and inorganic trace species. We then move on to a description of the basic chain reaction chemistry of the coupled $\text{O}_3/\text{OH}/\text{NO}_x/\text{CH}_4$ system that, to a large degree, controls the oxidizing capacity of the troposphere, that is, the ability of the troposphere to cleanse itself of pollutants. Finally, we provide examples of the complexity that results from the presence of C_2 and larger organic compounds by examining the oxidation mechanisms of ethane and isoprene which is the single most important organic compound emitted into the atmosphere by the terrestrial biosphere. One topic of enormous current interest that we mention in the context of isoprene oxidation and condensed-phase oxidation processes but do not discuss in detail is the role of radical chemistry in the generation of secondary organic aerosol (SOA). A detailed review article entitled "The formation, properties and impact of SOA: Current and emerging issues" is a good source of additional information about SOA for interested readers.⁷⁵

3.1 The Importance of HO_x Radicals in Tropospheric Chemistry

We saw in the previous section that ozone is the single most important chemical species in stratospheric chemistry. Similarly, the hydroxyl radical (OH) is widely considered to be the key species in tropospheric chemistry. The hydroxyl radical is often referred to as the *atmospheric cleansing agent* because reaction with OH initiates the tropospheric degradation of numerous organic and inorganic pollutants. The O–H bonds in water are stronger than most C–H bonds in organic molecules, and OH readily abstracts hydrogen from a majority of both organic and inorganic molecules where the abstraction reaction is energetically favorable. Hydroxyl radicals also add to unsaturated organics and react with most radicals and some closed-shell species

by addition, addition/elimination, or oxygen transfer pathways. The importance of OH as a tropospheric oxidant was first recognized in the early 1970s when model calculations were carried out demonstrating that photolysis of ozone at wavelengths long enough to penetrate into the troposphere could lead to OH production at daytime steady-state levels of around 10^6 molecules cm^{-3} via the following mechanism:^{76,77}

Production of $\text{O}(^1\text{D})$ from O_3 in the troposphere occurs following absorption of radiation within the approximate wavelength range of 300–340 nm. The weak spin-forbidden channel (3b), which has been demonstrated only recently,⁷⁸ is significant because it occurs at longer wavelengths than the spin-allowed channel (3a) and the solar actinic flux increases significantly with increasing wavelength over the wavelength range of interest. The relevant O_3 absorption cross sections and quantum yields for quantitatively evaluating the $\text{O}(^1\text{D})$ production rate are well established.^{3,79} Rate coefficients for reactions (36)–(38) are also well-established; reaction (38) occurs on essentially every encounter between $\text{O}(^1\text{D})$ and H_2O , and $k_{38} \sim 5 k_{37} \sim 6 k_{36}$.^{3,4} Applying the steady-state approximation to the short-lived intermediate $\text{O}(^1\text{D})$ leads to the following expression for the OH production rate, P_{OH} :

$$P_{\text{OH}} = 2k_{38}(J_{3a} + J_{3b})[\text{H}_2\text{O}][\text{O}_3]/(k_{36}[\text{N}_2] + k_{37}[\text{O}_2] + k_{38}[\text{H}_2\text{O}])$$

As in our discussion of stratospheric radical chemistry, it is useful to consider the HO_x ($\equiv \text{OH} + \text{HO}_2$) radical family in our discussion of tropospheric chemistry since these two radicals interconvert much more rapidly than they are produced (predominantly via reaction (38) as described above) or destroyed. The most important HO_x radical interconversion reactions are thought to be the

following:^{1,80}

The CH_3 product of reaction (42) is converted to HO_2 via a sequence of reactions, which is discussed in detail in Section 3.3, where it will be emphasized that the reactions of OH with CO and CH_4 , reactions (39) [(39a) + (39b)] and (42), are two of the most important reactions in all of tropospheric chemistry because they are not only the dominant tropospheric loss processes for CO and CH_4 , respectively, but they are also the two most important tropospheric removal pathways for OH. Under typical tropospheric conditions, a steady-state condition is rapidly established by the above interconversion reactions where HO_2 concentrations exceed OH concentrations by 1–2 orders of magnitude.^{81,82}

Loss of HO_x radicals in the troposphere occurs primarily via the following radical–radical reactions:

Reaction (47) plays a significantly different role in tropospheric chemistry than it does in stratospheric

chemistry. Nitric acid (HONO_2) is a reservoir species under most stratospheric conditions, although it becomes more of a sink species in the presence of PSCs. In the troposphere, nitric acid is a sink species since it is removed by (essentially irreversible) heterogeneous processes on a timescale that is short compared to the timescales for photolysis or reaction with OH.

As mentioned above, photochemical models that consider the OH production and loss processes described above predict daytime OH concentrations of about $10^6 \text{ molecules cm}^{-3}$. Major efforts to measure OH in the atmosphere began in the 1970s, but it was not until around 1990 that unequivocal direct measurements of OH were accomplished. Two of the most successful techniques for fast response measurements of OH are laser-induced fluorescence, which directly detects the OH molecule,⁸³ and chemical ionization mass spectrometry, which detects isotopically labeled H_2SO_4 formed by titrating OH with isotopically labeled SO_2 in the presence of O_2 and H_2O .⁸⁴ In addition, CH_3CCl_3 (1,1,1 trichloroethane, methyl chloroform) has been used as a chemical tracer to deduce the average tropospheric OH concentration.^{85–87} Methyl chloroform has no natural sources; it enters the atmosphere only as a result of industrial activity and, with the exception of a small ocean sink that can be quantitatively accounted for, its only tropospheric loss mechanism is reaction with OH. The temperature-dependent kinetics of the $\text{OH} + \text{CH}_3\text{CCl}_3$ reaction are well established.³ Since methyl chloroform is long-lived in the troposphere, it is uniformly distributed. Hence, gas chromatographic measurements at remote sites can be employed in conjunction with sophisticated models that make use of knowledge about sources and sinks to deduce the average tropospheric OH concentration. The result is very close to the value $1 \times 10^6 \text{ molecule cm}^{-3}$ originally predicted in the 1970s.^{76,77,85–87}

Methyl chloroform is sufficiently long-lived that a significant fraction of it is transported to the stratosphere where it can be a significant anthropogenic source of ozone-destroying chlorine. As a result, methyl chloroform is one of the chemical species that has been phased out of industrial production according to the Montreal protocol, an agreement between industrialized nations to protect the stratospheric ozone layer through elimination of the use of chlorine- and bromine-compounds with long enough

lifetimes to be transported to the stratosphere.^{10,88} Levels of methyl chloroform in the troposphere are dropping rapidly and will become too low to measure in the near future. Hence, the search is on for a replacement tracer that can be used to monitor the time evolution of the average tropospheric OH concentration.

3.2 Other Important Tropospheric Oxidants

Although OH is the single most important oxidant in tropospheric chemistry, many other species also play a role in initiating the degradation of both naturally occurring chemical species and anthropogenic pollutants. In this section, we identify and briefly discuss the chemistry of the most important oxidation initiators other than OH.

3.2.1 Nitrate Radical (NO_3)

The primary source of NO_3 radicals in the atmosphere is the reaction of NO_2 radicals with ozone.

Reaction (49) is relatively slow ($k_{49} = 3.2 \times 10^{-17} \text{ cm}^3 \text{ molecule}^{-1} \text{ s}^{-1}$ at 298 K),³ occurring on a timescale of several hours under typical tropospheric conditions. The NO_3 radical absorbs strongly throughout the visible region of the spectrum, and photodissociation quantum yields are high at all wavelengths shorter than 600 nm.³ Hence, the characteristic time for destruction of NO_3 by photolysis under daytime atmospheric conditions is only a few seconds and, as a result, NO_3 is of little importance in daytime atmospheric chemistry. However, NO_3 production via reaction (49) does not require sunlight, and NO_3 is thought to play a key role as a nighttime tropospheric oxidant. At night, loss of NO_3 occurs via reversible conversion to N_2O_5 coupled with loss of N_2O_5 via its heterogeneous hydrolysis reaction:

Although NO_3 is less reactive than OH, its nighttime concentrations can significantly exceed daytime

OH concentrations, particularly in dry, polluted environments like Southern California where NO_x levels are high and the hydrolysis sink reaction (30) is slow. The nitrate radical reacts rapidly with NO_x radicals, substituted alkenes, and organic sulfides, and it undergoes relatively slow hydrogen transfer reactions with organic compounds possessing relatively weak C–H bonds such as aldehydes and tertiary alkanes. Two extensive reviews covering the reaction kinetics, reaction mechanisms, spectroscopy, and atmospheric impact of the nitrate radical are available in the literature.^{89,90}

3.2.2 Ozone

We have seen above that ozone plays key roles as a source of HO_x radicals and in the interconversion of XO_x radicals ($\text{X} = \text{H}, \text{N}, \text{Cl}, \text{Br}, \text{I}$). In the troposphere, ozone also reacts via addition/elimination pathways with unsaturated organic compounds, and reaction with ozone is the single most important tropospheric degradation pathway for some alkenes.⁹¹ Over the last two decades, it has become clear that ozone reactions with alkenes produce OH radicals.^{92,93} It is now thought that ozone/alkene reactions represent a significant source of HO_x radicals under daytime conditions in some environments and a dominant source of HO_x radicals at night.⁹² The mechanism of an important example, the reaction of ozone with isoprene ($\text{CH}_2=\text{C}(\text{CH}_3)\text{CH}=\text{CH}_2$), is discussed in Section 3.4.

3.2.3 Halogen Radicals

The chemistry of ClO_x radicals in the troposphere differs from that in the stratosphere in two important ways: (i) the source compounds that photolyze to generate Cl atoms in the stratosphere are stable toward photolysis by radiation that penetrates into the troposphere; (ii) whereas in the stratosphere nearly all Cl atoms that are produced react with ozone, in the troposphere most Cl atoms are destroyed by reaction with organics. As a result, ClO_x radicals are largely ineffective at catalyzing ozone destruction in the troposphere. However, chlorine atoms react rapidly with saturated organics by hydrogen abstraction and also react rapidly with

unsaturated organics by addition. Rate coefficients for Cl + organic reactions are typically quite large, often exceeding the corresponding OH + organic rate coefficient by an order of magnitude or more.^{3,5} Hence, if sources are large enough to maintain Cl concentrations greater than ~1% of the OH concentration, then Cl would be an important tropospheric oxidant for many organics. There now exists strong evidence that Cl concentrations can approach 10^5 atoms cm^{-3} at both polar- and mid-latitudes in the marine boundary layer (MBL)^{94–96} where sea-salt aerosol particles provide a large source of Cl^- that can be converted into gas-phase, photochemically labile chlorine species such as Cl_2 , ClNO , or ClNO_2 by heterogeneous reactions occurring either in the bulk or on the surface of aqueous particles.^{97–100} Gas-phase reactants that have been shown to undergo heterogeneous reactions that lead to production of gas-phase Cl atoms include OH, ClONO_2 , N_2O_5 , NO_2 , and HNO_3 .^{97–100} Significant levels of $\text{ClNO}_2(\text{g})$ have recently been observed in Colorado: that is, far removed from the availability of sea-salt aerosol.¹⁰¹ In addition to the heterogeneous chemistry discussed above, some Cl can be generated via purely gas-phase chemistry. Some HCl product of Cl hydrogen abstraction reactions reacts with OH to regenerate Cl atoms (the remaining HCl is removed by uptake into aqueous droplets). Also, while only a small fraction of Cl reacts with O_3 to generate ClO (reaction 11), that Cl is recycled either directly via the $\text{ClO} + \text{NO}$ reaction (24) or indirectly via photolysis of HOCl (reaction 10) that is formed as a product of the $\text{ClO} + \text{HO}_2$ reaction (9). Over the last decade, it seems that the more we have learned about tropospheric chlorine chemistry, the more important Cl has appeared to become as a tropospheric oxidant.

Similar to the situation with chlorine, the source compounds that photolyze to generate Br atoms in the stratosphere are, for the most part, stable toward photolysis by radiation that penetrates into the troposphere. However, unlike chlorine, atomic bromine does not react rapidly with most organic compounds by hydrogen abstraction because only the weakest C–H bonds are weaker than the H–Br bond. Like chlorine, atomic bromine can react with unsaturated organics by addition to form a bromoalkyl radical. However, the C–Br bond in a given bromoalkyl radical is much weaker than the C–Cl bond in the corresponding chloroalkyl radical. The C–Br bond

strength in $^{\bullet}\text{CH}_2\text{CH}_2\text{Br}$ is only 29 kJ mol^{-1} .^{102,103} Substitution of electron-withdrawing groups for the H atoms in $^{\bullet}\text{CH}_2\text{CH}_2\text{Br}$ reduces the C–Br bond strength, while substitution of electron-donating groups has the opposite effect. Conjugated dialkenes such as 1,3-butadiene and isoprene form particularly strongly bound bromine adduct radicals; the most stable Br–isoprene adduct radical has a C–Br bond strength of 70 kJ mol^{-1} .¹⁰⁴ The “effective rate coefficients” for Br + olefin reactions under tropospheric conditions depend on the addition rate coefficient and on the competition between unimolecular decomposition and O_2 addition for consumption of the Br–olefin radical adduct. These effective rate coefficients can have complex dependences on temperature, pressure, and $[\text{O}_2]$, but appear to become quite fast under conditions where the O_2 reaction dominates the competition for removal of the Br–olefin radical adduct.¹⁰⁵

Because Br atoms are less reactive with organics than Cl atoms, Br atoms can participate in catalytic cycles that destroy ozone. The most important catalytic cycle under typical tropospheric conditions is the $\text{BrO} + \text{HO}_2$ cycle, that is, reactions (6) and (12)–(14). As in the case of chlorine, heterogeneous reactions are required to maintain significant levels of BrO_x radicals. During the late 1980s, field observations in the Arctic observed a correlation between extreme springtime sea-level ozone depletion events and high levels of bromine in filter samples containing collected particulate matter.¹⁰⁶ It is now thought that the following heterogeneous reaction scheme involving HOBr that is generated via reaction (12) and taken up into the condensed phase can occur on cold, briny surfaces to produce Br_2 , which escapes to the gas phase and is readily photolyzed to generate Br atoms.^{100,107}

The sequence of reactions (51)–(53) is sometimes referred to as the *bromine explosion*. It results in very high BrO_x levels which, in turn, allow the following catalytic cycle to make a significant contribution to ozone depletion:

The BrO self-reaction actually occurs via two different channels, one as written above and the other to form $\text{Br}_2 + \text{O}_2$. However, Br_2 photodissociates rapidly under tropospheric conditions, so for understanding the role of reaction (55) in tropospheric chemistry it can be assumed to proceed entirely as written above.

In addition to its role in polar boundary layer ozone depletion events and as an oxidant for some unsaturated organics (see above), atomic bromine is thought to be the dominant tropospheric sink species for elemental mercury.^{108,109} Also, BrO radicals are thought to play an important role as a sink species for dimethylsulfide (DMS, CH_3SCH_3),¹¹⁰ emission of which from the oceans is the largest natural source of sulfur to the atmosphere.¹¹¹

A major difference between the tropospheric chemistry of iodine and that of other halogens is that organic iodine compounds can be photodissociated by relatively long-wavelength radiation that is transmitted through the ozone layer to the earth's surface. As a result, catalytic destruction of ozone by iodine can occur without the requirement for generation of photochemically labile IO_x precursors by heterogeneous chemistry (although such production undoubtedly does occur to some extent). A summary of our current understanding of gas-phase tropospheric iodine chemistry is shown in Figure 5. Several catalytic cycles can readily be identified via which IO_x radicals can destroy ozone. The rate-limiting steps in these cycles are the reactions of IO with HO_2 , NO_2 , BrO, IO, and DMS. As discussed above when considering tropospheric HO_x chemistry, the $\text{IO} + \text{HO}_2$ reaction (43) also is of importance because of its impact on the HO_2/OH concentration ratio in some parts of the troposphere. The IO self-reaction is considerably faster than the BrO or ClO self-reactions and occurs via four different channels:³

Figure 5 Schematic overview of gas-phase tropospheric iodine chemistry ($X = \text{Br}, \text{I}$). [Adapted (with modifications) from Refs 100 and 159.]

Since I_2 photolyzes rapidly under tropospheric conditions, the production of IO via the reaction of atomic iodine with O_3 coupled with IO loss via reactions (56a), (56b), or (56c) constitutes a catalytic cycle for ozone destruction. The role of reaction (56c) in ozone destruction depends on the fate of OIO, which is currently controversial. The species OIO has a strong absorption band in the 480–650-nm wavelength range. Crowley and coworkers report that quantum yields for production of oxygen atoms and iodine atoms from OIO photolysis are very small.^{112,113} On the other hand, Plane and coworkers report that iodine atoms are formed with unit quantum yield.¹¹⁴ The addition product of the IO self-reaction, namely, I_2O_2 , has been suggested as a precursor to new particles whose formation is correlated with the presence of high levels of iodine, particularly in coastal environments at low tide, that is, under conditions where microalgae are exposed to the atmosphere.^{115–118}

In summary, although IO_x radicals are largely unimportant as direct initiators of the oxidation of tropospheric trace gases, they do have an important indirect effect through their impact on ozone levels. The reaction of IO radicals with DMS does occur with a significant rate coefficient,³ and may represent a non-negligible sink for DMS in some coastal marine environments. In addition, the

role of iodine in new particle formation is a topic of great current interest.

3.2.4 Aqueous-Phase Oxidants

An overview of the atmospheric condensed phase was presented in Section 1.1. Potentially important atmospheric aqueous-phase oxidants include ozone, peroxides, and transition-metal ions, as well as a number of radical species including OH, HO₂, O₂^{•−}, SO_x^{•−} ($x = 3-5$), X₂^{•−} (X = Cl, Br), and NO₃. Aqueous-phase oxidation can be an important atmospheric loss process for chemical species that are highly soluble in water. Herrmann and coworkers have reviewed the state of knowledge of the kinetics of aqueous-phase radical reactions of atmospheric interest,^{119,120} and have also developed aqueous-phase reaction mechanisms for use in modeling atmospheric chemistry.^{121,122}

Perhaps the most important aqueous-phase chemical transformation in atmospheric chemistry is the oxidation of S(IV) to S(VI). The gas-phase reaction of OH with SO₂, which is the rate-limiting step in formation of H₂SO₄(g), an important precursor to new particles in both the troposphere and stratosphere,^{1,9,10} is relatively slow, occurring on a timescale of several weeks. Under most tropospheric conditions, SO₂ is removed from the gas phase primarily by uptake into aqueous droplets and subsequent aqueous-phase oxidation. The dominant aqueous-phase oxidants for S(IV) are thought to be H₂O₂ at relatively low pH and O₃ at relatively high pH.⁹ The OH radical is also thought to make a significant contribution to S(IV) oxidation in the aqueous phase via its reactions with HSO₃^{•−}, SO₃^{2•−}, and deprotonated forms of HOCH₂SO₃H (hydroxy methane sulfonic acid, HMSA) which is formed via aqueous-phase addition of S(IV) to dissolved formaldehyde.^{9,123} In relatively polluted environments, a significant fraction of S(IV) can exist as HMSA, which is relatively stable toward reaction with H₂O₂ and O₃ but reacts rapidly with OH.^{9,123,124} Aqueous-phase reaction with radicals is also thought to be important in the atmospheric transformation chemistry of the DMS oxidation products dimethyl sulfoxide (CH₃S(O)CH₃, DMSO), methane sulfinic acid (CH₃S(O)OH, MSIA), dimethyl sulfone (CH₃SO₂CH₃), and methane sulfonic acid (CH₃SO₂OH, MSA).¹²⁴⁻¹²⁸

Finally, we note that there is currently a great deal of interest in establishing the role that aqueous-phase radical chemistry plays in the formation of SOA.^{75,129}

3.3 The OH-Initiated Chain Oxidation of CO and CH₄

In this section, we discuss the single most important aspect of tropospheric radical chemistry, namely, the chain reactions that maintain the troposphere's ability to cleanse itself of pollutants. As mentioned in Section 3.1, it has been known since the 1970s that the OH radical is the key oxidant in the troposphere and that the two most important sink reactions for OH under a majority of tropospheric conditions are its reactions with CO and methane (CH₄).^{76,77,130} In units of cm³ molecule^{−1} s^{−1}, the currently recommended rate coefficient for the OH + CO reaction is $k_{39} = 1.3 \times 10^{-13} [1 + 0.6P(\text{bar})] \exp(0/T)$, while the currently recommended rate coefficient for the OH + CH₄ reaction is $k_{42} = 2.2 \times 10^{-12} \exp[-1740/T(\text{K})]$.^{3,5} Reaction (39) is the dominant atmospheric loss mechanism for CO, and reaction (42) is the dominant atmospheric loss mechanism for CH₄.¹ Methane is sufficiently long-lived that it is uniformly distributed throughout the troposphere with a mixing ratio of 1.7 ppmv (parts per million by volume). The OH + CO rate coefficient is significantly larger than the OH + CH₄ rate coefficient and, as a result, the tropospheric lifetime of CO is considerably shorter than that of CH₄. Hence, CO is not as uniformly distributed in the troposphere as CH₄. In particular, CO levels are significantly higher in the Northern Hemisphere than in the Southern Hemisphere because combustion sources of CO are found primarily at mid-latitudes in the Northern Hemisphere. Tropospheric mixing ratios of CO are typically more than an order of magnitude smaller than that of CH₄. Assuming a CO mixing ratio of 0.1 ppmv suggests the following lifetimes for OH toward loss by reaction with CO and CH₄ at $T = 298 \text{ K}$: 1.9 s for loss by reaction with CO and 3.4 s for loss by reaction with CH₄.

At the time when OH was first identified as the key tropospheric oxidant and ozone was identified as the photolytic precursor for OH,^{76,77} it was the generally held belief that the dominant source of ozone in the troposphere is transport down from

Figure 6 Schematic diagram showing the mechanism for the OH-initiated chain oxidations of carbon monoxide and methane with emphasis on “high- NO_x ” conditions.

the stratosphere. Making such an assumption and using updated estimates for (i) the rate of transport of ozone downward through the tropopause and (ii) the rates of emission of CO and CH_4 into the troposphere leads to the conclusion that, in the absence of additional sources, OH would be titrated, thus allowing pollutants that are removed primarily via reaction with OH (including CO and CH_4) to reach high levels with catastrophic environmental implications.¹ The reason why this doomsday scenario does not actually happen is that OH reactions with CO and CH_4 initiate chain reaction chemistry that, in a majority of tropospheric environments, produces more O_3 and OH than are destroyed in the initiation process. The chain oxidations of CO and CH_4 are summarized schematically in Figure 6, and are discussed in detail below. While extremely important, this chemistry is now well understood and is covered in detail in atmospheric chemistry textbooks.^{1,9–11} Hence, many statements are made below without providing references.

3.3.1 Oxidation of Carbon Monoxide

Oxidation of CO to CO_2 in the troposphere occurs via reactions (39)–(41). The CO_2 coproduct HO_2

reacts predominantly with NO (reaction 22) and O_3 (reaction 8) under a majority of tropospheric conditions. Reactions (8) and (22) both regenerate OH to propagate the chain reaction, but the impact of CO oxidation on ozone levels depends critically on which of the two reactions predominates. If reaction (22) is the dominant pathway for conversion of HO_2 to OH, the OH coproduct is NO_2 whose dominant loss pathway is photolysis to produce ground-state oxygen atoms which combine with O_2 to generate ozone (reaction 23 followed by reaction 2). At this point, it is worth noting that the mechanism (23) followed by (2) is the dominant pathway for photochemical production of ozone in the troposphere. Whenever the oxidation of a tropospheric trace species results in NO_2 production, ozone is generated via NO_2 photodissociation. In the limiting scenario where all HO_2 reacts with NO, the net reaction describing CO oxidation, that is, the sum of reactions (39a), (39b), (40), (41), (22), (23), and (2) is reaction (57), whereas in the limiting scenario where all HO_2 reacts with O_3 , the net reaction describing CO oxidation is the sum of reactions (39a), (39b), (40), (41), and (8), that is, reaction (58).

Under “high- NO_x ” conditions, CO oxidation results in ozone production (reaction 57) whereas under “low- NO_x ” conditions, CO oxidation results in ozone destruction (reaction 58).

On the basis of currently recommended rate coefficients,^{3,4} the ratio k_{22}/k_8 varies from 4300 at 300 K to 15 000 at 200 K. At 280 K, a reasonable estimate for the average temperature at which the OH + CO reaction occurs in the troposphere, $k_{22}/k_8 = 5200$. Assuming a typical ozone mixing ratio of 40 ppbv, the approximate NO mixing ratio at which the rates of reactions (57) and (58) are equal is 8 pptv (parts per trillion by volume), a level that is exceeded in all but the most pristine regions of the troposphere. In virtually all terrestrial environments of the Northern Hemisphere, oxidation of CO results in ozone production.

3.3.2 Oxidation of Methane

Methane oxidation in the troposphere is initiated by the hydrogen abstraction reaction with OH, reaction

(42). Atomic chlorine also abstracts hydrogen from methane (reaction 27) at a rate that may compete with the OH reaction under MBL conditions. All methyl radicals produced from reactions (42) and (27) react with O₂ on a sub-microsecond timescale to produce methylperoxy radicals, CH₃O₂.

The tropospheric chemistry of CH₃O₂ is similar to that of HO₂ with one important exception. Whereas the HO₂ + O₃ reaction dominates HO₂ removal under low-NO_x conditions, the CH₃O₂ reaction with O₃ is too slow to be important in the troposphere.³ Instead, CH₃O₂ reacts with other peroxy radicals (predominantly HO₂) under low-NO_x conditions, and the competition for removal of CH₃O₂ is between reactions (60) and (61).

For reasons discussed in Section 3.3.1, the occurrence of reaction (60) results in ozone production. At 280 K, a reasonable estimate for the average temperature at which the OH + CH₄ reaction occurs in the troposphere, $k_{60}/k_{61} = 1.4$.³ Daytime levels of HO₂ in the troposphere are somewhat variable but, as discussed in Section 3.1, 2 pptv is a reasonable estimate for the HO₂ mixing ratio, suggesting that reaction (60) becomes the dominant CH₃O₂ removal pathway when the NO mixing ratio exceeds 10 pptv.

Under tropospheric conditions, the carbon-containing products of reactions (60) and (61), namely, methoxy radical (CH₃O) and methyl hydroperoxide (CH₃OOH), undergo the following reactions:

Reaction (62) occurs on a millisecond timescale under tropospheric conditions and completely dominates the removal of CH₃O. Methyl hydroperoxide is removed by photolysis and OH reaction at

competitive rates; its typical lifetime is around 1 day. Methyl hydroperoxide is less soluble in water than hydrogen peroxide, and uptake into the aqueous phase is a relatively minor loss process.

Examination of the mechanism of reactions (59)–(65) shows that formaldehyde (H₂CO) is formed with unit yield from methane oxidation. Ignoring a relatively minor aqueous-phase sink, formaldehyde is lost primarily by the following processes:

The H atom product of reaction (68b) is converted to HO₂ via reaction (40) on a sub-microsecond timescale, while the H₂ product of reaction (68b) has a tropospheric lifetime of about 5 years toward loss by reaction with OH.³ The radical channel (68b) for formaldehyde photolysis is favored at shorter wavelengths (300–320 nm), while the molecular channel (68a) is favored at longer wavelengths (320–350 nm).³ Under typical daytime conditions, the formaldehyde lifetime is a few hours and $k_{68a} \sim 2k_{68b} \sim 4k_{66}$. Formaldehyde degradation produces CO with unit yield and also results in the production of some HO_x radicals.

To get a picture of how methane oxidation affects the troposphere's ability to cleanse itself of pollutants, it is useful to examine two limiting scenarios that bracket the actual behavior. In limiting scenario 1, we assume "high-NO_x" conditions, that is, all CH₃O₂ and HO₂ radicals are assumed to react with NO via reactions (60) and (22), and we also assume that formaldehyde degradation occurs entirely via the radical-producing photolysis channel (68b); this scenario maximizes the production of O₃ and HO_x radicals from methane oxidation. Summing all the relevant reactions gives the following balanced chemical equation for oxidation of methane to CO₂:

In limiting scenario 2, we assume low-NO_x conditions, that is, all CH₃O₂ reacts with HO₂ via reaction

(61) and all HO_2 reacts with O_3 via reaction (8), and we also assume that all CH_3OOH reacts with OH via reaction (63b) and all formaldehyde reacts with OH via reaction (66); this scenario results in loss of O_3 and HO_x radicals via methane oxidation. Summing all the relevant reactions gives the following balanced chemical equation for oxidation of methane to CO_2 :

3.3.3 The Bottom Line

We generally think of NO as an unwanted pollutant that is emitted into the atmosphere in large quantities from combustion sources. However, the above discussion of CO and methane oxidation shows that maintenance of the atmosphere's ability to cleanse itself of pollutants depends critically on the availability of enough NO (tens of pptv) to make reactions (22) and (60) the most important removal mechanisms for HO_2 and CH_3O_2 radicals, respectively. The currently accepted ozone budget is much different from the budget that was accepted several decades ago. It is now believed that $83 \pm 10\%$ of tropospheric ozone is produced photochemically *in situ* while only $17 \pm 10\%$ is transported down from the stratosphere.¹ The oxidizing capacity of the troposphere will evolve in the future as levels of CO , CH_4 , and NO_x change.

3.4 Tropospheric Oxidation of Organics with Two or More Carbon Atoms

The radical chemistry involved in the tropospheric oxidation of organic molecules becomes progressively more complex as the number of carbon atoms in the organic increases. The complexity arises because (i) the number of different peroxy radicals ($\text{ROO}^\bullet$) that can be formed increases as the size of the organic increases and (ii) the number of loss pathways for each alkoxy radical ($\text{RO}^\bullet$) increases as the number of carbons in $\text{RO}^\bullet$ increases. Page and time limitations prevent us from covering organic oxidation mechanisms with the level of detail that would be desirable. For more information, interested readers are referred to an extensive review by Atkinson.¹³¹ In this section, we discuss

the oxidation of two important examples, ethane and isoprene, the single most important biogenic hydrocarbon in tropospheric chemistry.

3.4.1 Oxidation of Ethane and the Role of PAN in Tropospheric Chemistry

A schematic diagram summarizing the tropospheric oxidation of ethane is shown in Figure 7. Similar to methane, oxidation of ethane is initiated by hydrogen abstraction reactions with OH and Cl , with OH the dominant oxidant. Conversion of the ethyl radical ($\text{CH}_2\text{CH}_3^\bullet$) to ethoxy ($\text{CH}_3\text{CH}_2\text{O}^\bullet$) follows an analogous path to that described in Section 3.3.2 for conversion of methyl to methoxy. Unlike $\text{CH}_3\text{O}^\bullet$, which reacts exclusively with O_2 under tropospheric conditions, $\text{CH}_3\text{CH}_2\text{O}^\bullet$ is removed competitively by reaction with O_2 and C–C bond fission. The bond fission reaction produces $\text{H}_2\text{CO} + \text{CH}_3^\bullet$, both of which are further oxidized as discussed in Section 3.3.2. The $\text{CH}_3\text{CH}_2\text{O}^\bullet + \text{O}_2$ reaction produces acetaldehyde (CH_3CHO). Acetaldehyde photolyzes more slowly and reacts with OH more rapidly than formaldehyde, so OH reaction, which occurs almost exclusively via abstraction of the weakly bound aldehydic hydrogen, dominates acetaldehyde removal. The $\text{OH} + \text{acetaldehyde}$ reaction produces $\text{CH}_3\text{CO}^\bullet$, which, like all carbon-centered radicals, rapidly adds O_2 to produce acetylperoxy radical $\text{CH}_3\text{C}(\text{O})\text{OO}^\bullet$. Like all peroxy radicals, acetylperoxy reacts primarily with NO and/or HO_2 .

Whereas CH_3O_2 and $\text{CH}_3\text{CH}_2\text{O}_2$ reactions with NO_2 are relatively unimportant in tropospheric chemistry because the nitrates formed decompose rapidly, the organic nitrate formed from acetylperoxy + NO_2 is relatively stable; this organic nitrate is known as *peroxyacetyl nitrate* and is commonly referred to as *PAN* by atmospheric chemists. In the troposphere, *PAN* exists in equilibrium with acetylperoxy radicals and NO_2 , and the acetylperoxy + NO reaction represents the dominant *PAN* loss process. Both $\text{PAN} + \text{OH}$ and *PAN* photolysis are very slow under tropospheric conditions. If *PAN* is formed in or transported to a relatively low-temperature tropospheric environment, it becomes stable and can be transported over long distances, and then release NO_x when it finds its way into a warmer environment.

Figure 7 Schematic diagram showing mechanisms for tropospheric ethane oxidation and PAN formation.

Most tropospheric NO_x is anthropogenic in origin; the two largest sources are fossil fuel combustion and biomass burning.¹ The tropospheric lifetime of NO_x is around 1 day, so NO_x does not live long enough to be transported over long distances from source regions. It is generally thought that PAN plays a key role in transporting NO_x to remote regions of the troposphere, thereby helping to maintain the oxidizing capacity of these remote regions.¹ PAN or substituted PANs with the general formula RC(O)OONO_2 can be formed as products of the tropospheric oxidation of numerous organics; as long-lived reservoirs for NO_x radicals, these compounds play an important role in tropospheric chemistry.

3.4.2 Oxidation of Isoprene

Isoprene (2-methyl-1,3-butadiene, $\text{CH}_2=\text{C}(\text{CH}_3)\text{CH}=\text{CH}_2$) is produced and emitted into the atmosphere in large quantity by deciduous plants.¹³² The isoprene flux into the atmosphere is larger than that of any hydrocarbon other than methane,¹³³ and isoprene is much more reactive than methane.^{3,5}

At 298 K, rate coefficients for isoprene reactions with OH , NO_3 , O_3 , and Cl (in units of $10^{-13} \text{ cm}^3 \text{ molecule}^{-1} \text{ s}^{-1}$) are 1000, 7.3, 0.00013, and 4100, respectively.³ All reactions proceed by addition pathways, although the Cl reaction also has a minor hydrogen abstraction channel.³ Under typical tropospheric conditions, reaction with OH dominates isoprene removal during daytime.¹³⁴ At night, NO_3 dominates isoprene removal in polluted environments, but O_3 dominates in unpolluted environments.^{134,135} Nighttime NO_3 can be competitive with daytime OH as an isoprene oxidant in polluted environments.^{134,135} Chlorine atoms may be a significant isoprene oxidant in some marine environments.¹³⁴ Product studies carried out under high- NO_x conditions in air, as summarized in a 2003 review,¹³⁴ suggest the following yields of stable first-generation products from the OH -initiated oxidation of isoprene: H_2CO , 0.60 ± 0.07 ; methyl vinyl ketone ($\text{CH}_3\text{C(O)CH}=\text{CH}_2$, MVK), 0.33 ± 0.07 ; methacrolein ($\text{CH}_2=\text{C}(\text{CH}_3)\text{CHO}$, MACR), 0.23 ± 0.06 ; organic nitrates, 0.09 ± 0.05 ; 3-methylfuran, 0.04 ± 0.02 . Under low- NO_x conditions, the OH -initiated oxidation of isoprene in air produces as first-generation products the two hydroxy hydroperoxides $\text{CH}_2=\text{C}(\text{CH}_3)\text{CH}(\text{OOH})$

CH_2OH and $\text{HOCH}_2\text{CH}=\text{C}(\text{CH}_3)\text{CH}_2\text{OOH}$ with a combined yield in excess of 0.7.¹³⁶ For the O_3 + isoprene reaction in the presence of an OH scavenger (needed for reasons discussed below), the yields are H_2CO , 0.90; MVK, 0.16 ± 0.02 ; and MACR, 0.40 ± 0.04 .¹³⁴ Organic nitrates are the major observed products of the NO_3 + isoprene reaction, although small amounts of H_2CO , MVK, and MACR are also produced.¹³⁴

In a number of recent field studies carried out in forested regions where isoprene emissions are high, the measured OH concentrations were found to significantly exceed those expected on the basis of model simulations that employed chemical mechanisms as they were known in 2007.^{137–140} The search for an explanation for the discrepancy between models and measurements has led to major experimental and theoretical efforts to obtain an improved understanding of the isoprene oxidation mechanism.^{136, 141–153} In particular, it has been recognized that the discrepancy between models and measurements would be alleviated if the OH-initiated oxidation of isoprene were found to result in significant regeneration of OH radicals. Production of OH from isoprene oxidation has important implications for atmospheric chemistry in low- NO_x regions with high levels of vegetation such as, for example, the Amazon basin, since this would provide a mechanism for maintaining the oxidizing capacity of the atmosphere even in the absence of net photochemical production of ozone.

Addition of OH to isoprene can occur at any of the four carbons on the 1,3-butadiene backbone. It is well established that addition at the outer carbons is favored, with more than 60% of the initial addition occurring at the 1-position and about 30% occurring at the 4-position.^{141, 143, 154} Theoretical calculations suggest that 1-OH addition produces cis and trans conformers with equal probability whereas 4-OH addition produces 70% cis conformer.¹⁴³ The products of OH addition at the 1- and 4-positions are allyl-resonance-stabilized and, as a result, six different peroxy radicals can be generated by addition of O_2 to the four initially formed adduct radicals.¹⁴⁴ Hydrogen abstraction from the methyl group (not believed to be important for OH + isoprene but significant for Cl + isoprene) leads to formation of a seventh peroxy radical. In order to reproduce OH levels observed in the field experiments cited above,^{137–140} which for the most part explored “low- NO_x ” environments, the peroxy

radicals formed from OH addition to isoprene in the presence of O_2 would have to undergo subsequent reactions that generated OH with a yield of around 0.5. Conventional wisdom, which suggests that the peroxy radicals are consumed primarily via bimolecular reactions with HO_2 and (to a lesser extent) organic peroxy radicals under low- NO_x conditions, seems incapable of rationalizing such a large yield of recycled OH.¹⁴³

Peeters and collaborators have recently reported theoretical studies where unimolecular pathways for isoprene peroxy radical transformations are identified that lead to significant OH generation.^{143, 144, 152, 153} Detailed chemical schemes for oxidation of the 1-OH and 4-OH conformers are presented in two of their papers,^{143, 152} and are not reproduced here. However, their main findings are summarized below:

Under tropospheric conditions, the peroxy radicals have lifetimes of only tenths of a second toward thermal decomposition. The conditions of most laboratory studies are such that peroxy radicals probably undergo bimolecular reaction on a timescale that is short compared to the thermal dissociation time, but in the atmosphere the peroxy radicals have lifetimes of tens of minutes and, therefore, are in thermal equilibrium with the OH-isoprene adduct radicals, rapidly cycling between the two. This allows the bulk of the radical pool to be funneled through the most reactive channels, which are predicted to be 1,6 hydrogen shifts in Z- δ -OH-peroxy radicals to form the hydroxy hydroperoxy radicals $^{\bullet}\text{CH}(\text{OH})\text{C}(\text{CH}_3)=\text{CHCH}_2\text{OOH}$ and $^{\bullet}\text{CH}(\text{OH})\text{CH}=\text{C}(\text{CH}_3)\text{CH}_2\text{OOH}$; these radicals rapidly react with O_2 to form HO_2 + hydroperoxy aldehydes that can rapidly photodissociate to generate OH. In addition, the radicals 1-OH-2-OO'-isoprene and 4-OH-3-OO'-isoprene are predicted to undergo 1,5 hydrogen shifts to generate OH + H_2CO + a second carbonyl compound (MVK or MACR); the net yield of OH via this pathway is estimated to be in the range 0.01–0.1.

The findings of Peeters and collaborators provide a plausible explanation for the large yields of recycled OH when isoprene is oxidized in the troposphere under low- NO_x conditions. Of course, their findings must be considered somewhat speculative until they are verified experimentally. The first step toward experimental verification of the theoretical findings has already been reported.¹⁴⁴

In addition to its role in maintaining the oxidizing capacity of the atmosphere under low- NO_x conditions, isoprene is also of considerable current interest because of its role in SOA formation. Seinfeld and collaborators have made major recent contributions toward understanding the role of isoprene in SOA formation.^{136,145,150,151,155} One key recent finding that impacts both SOA formation and OH recycling is the observation that, under low- NO_x conditions, dihydroxy epoxides are produced from secondary oxidation of the hydroxy hydroperoxides, and the dihydroxy epoxide coproducts are OH radicals.¹³⁶ The dihydroxy epoxides are quite soluble in water and are rapidly oxidized in the aqueous phase to form nonvolatile products; in this manner they contribute to SOA formation.¹⁵⁰ Similarly, MPAN ($\text{CH}_2=\text{C}(\text{CH}_3)\text{C}(\text{O})\text{OONO}_2$), a second-generation isoprene oxidation product under high- NO_x conditions that is formed via oxidation of MACR, has been identified as a key precursor to SOA formation in high- NO_x environments.¹⁵⁰

As discussed briefly above, the reaction of O_3 with isoprene is a key source of OH radicals at night in low- NO_x environments and during daytime in both low- NO_x and high- NO_x environments. A tutorial review of the gas-phase ozonolysis of alkenes has been recently published by Johnson and Marston,¹⁵⁶ and a high-quality experimental study of OH and HO_2 production from O_3 + isoprene has been recently reported by Malkin *et al.*, who find OH and HO_2 to be produced with essentially equal yields of 0.26 ± 0.03 .¹⁵⁷ The O_3 + isoprene reaction proceeds via addition of ozone across one of the double bonds to form a primary ozonide (a five-member ring structure containing the two carbon atoms that made up the double bond and the three oxygen atoms). Each of the two primary ozonides that can be formed from O_3 + isoprene decomposes by O–O bond fission to form two different pairs of Criegee biradical intermediate (CI) + carbonyl products. Hence, for O_3 + isoprene, four sets of products are generated via decomposition of primary ozonides: $\cdot\text{CH}_2\text{OO}\cdot + \text{CH}_2=\text{C}(\text{CH}_3)\text{CHO}$, $\text{CH}_2=\text{C}(\text{CH}_3)\text{C}\cdot\text{HOO}\cdot + \text{H}_2\text{CO}$, $\cdot\text{CH}_2\text{OO}\cdot + \text{CH}_2=\text{CHC}(\text{O})\text{CH}_3$, and $\text{CH}_2=\text{CHC}\cdot(\text{CH}_3)\text{OO}\cdot + \text{H}_2\text{CO}$. The CIs are formed hot, and stabilization competes with unimolecular decay of the hot CIs under tropospheric conditions. The stabilized biradicals can survive long enough to undergo bimolecular reactions.¹⁵⁶ Production of HO_x radicals is thought

to occur via unimolecular decay of hot CIs, but the detailed pathways remain rather uncertain.^{156,157}

4 CONCLUSION

The atmosphere is a complex photochemical reactor where a vast majority of the chemical transformations involve reactions of reactive free radicals that are generated by solar photolysis of stable precursors. This article has focused on radical chemistry in the lowest 50 km of the atmosphere, an altitude regime that contains about 99.9% of the atmospheric mass. The altitude regime of interest is divided into two layers, the lower altitude troposphere and the higher altitude stratosphere.

The stratosphere contains 90% of all atmospheric ozone, and this ozone protects the earth's biosphere from the harmful effects of ultraviolet radiation. Our discussion of stratospheric chemistry has focused on radical-catalyzed pathways for ozone destruction. It is clear that ClO_x and BrO_x radicals, which are present in the stratosphere largely as a result of human activity, contribute significantly to ozone loss at mid-latitudes and dominate the massive ozone loss observed in the springtime Antarctic lower stratosphere.

Tropospheric radical chemistry is extremely complex, owing largely to the presence in the troposphere of a multitude of organic compounds that are too short-lived to be transported to the stratosphere. Our discussion of tropospheric radical chemistry has focused on the complex chain reactions involving ozone, hydroxyl radicals, nitrogen oxide radicals, and organics that maintain the oxidizing power of the troposphere, that is, the ability of the troposphere to cleanse itself of pollutants. The chemistry of important radical initiators of the degradation of tropospheric pollutants was reviewed, and the atmospheric oxidation of two representative organics, ethane and isoprene was discussed in detail. Understanding the production of HO_x radicals from isoprene oxidation is an issue of significant current interest to the atmospheric chemistry community.

Looking to the future, there is currently intense interest in the atmospheric chemistry community in gaining a fundamental understanding of the chemistry of SOA formation. Gas-phase radical chemistry of large semivolatile organics is likely to be important in SOA formation as are aqueous-phase radical pathways.

Basic Concepts on Radical Chain Reactions

Michael S. Sherburn

*Australian Research Council Centre of Excellence for Free Radical Chemistry and Biotechnology,
Research School of Chemistry, Australian National University, Canberra, Australia*

1 FUNDAMENTAL CONCEPTS

1.1 Structure and Stability of Carbon-Centered Radicals

The three structures available to carbon-based radicals are depicted in Figure 1. These structures are classified by the number of ligands attached to the radical center.

If three ligands are present, most alkyl radicals have a planar geometry at carbon and the radical resides in a p orbital, orthogonal to this plane. In some instances, $R_3C^\bullet$ radicals prefer a pyramidal (sp^3 hybridized) shape, for example in geometrically and/or conformationally constrained systems such as the adamant-1-yl radical, or in electronically perturbed systems such as the trifluoromethyl radical (see **Analysis of Radicals by EPR and Structures and Reactivity of Radicals Followed by Magnetic Resonance**). Nevertheless, sp^2 hybridization and a trigonal planar shape is more common and, in this aspect, an $R_3C^\bullet$ radical is more akin to its one-electron-less carbocation counterpart (R_3C^+) than its one-electron-more carbanion congener (R_3C^-). An important consequence of the planar shape of $R_3C^\bullet$ radicals is that the configuration of a stereocenter will not be retained during a process that involves bond breaking/bond formation through a radical intermediate (i.e., $R_3C-X \rightarrow [R_3C^\bullet] \rightarrow R_3C-Y$).

When only two ligands are attached to a carbon radical, one of them must be joined through a double bond. Alkenyl, aryl, and acyl radicals are among the most important members of this family. These are also sp^2 hybridized $C^\bullet$ species but, in this case, the radical resides in an sp^2 orbital that is roughly in plane with the C and its two covalently bonded atoms. The shape of the molecule in the immediate vicinity of $C^\bullet$ is bent and, unless constrained in a small ring (as is the case in a phenyl radical, for example), inversion between the two “bent” forms is possible. The transition state for this inversion process has a local linear geometry at $C^\bullet$ with the radical in a p orbital, hence sp hybridized at $C^\bullet$.

Carbon radicals carrying a single substituent that is attached through a triple bond are much less common. In this case, the radical resides in an sp hybridized orbital and the radical has a linear shape.

Carbon radicals can be stabilized by both electronic and steric effects. Generally speaking, substituents that stabilize *either* carbocations *or* carbanions will stabilize a radical. The order of stability of simple alkyl radicals is $H_3C^\bullet < RH_2C^\bullet < R_2HC^\bullet < R_3C^\bullet$, hence alkyl radical stability follows carbocation stability (see **Radical Stability—Thermochemical Aspects**). In addition to this inductive electronic effect, orbital overlap with an adjacent π bond or lone pair also leads to increased stabilization; the simple resonance picture will suffice for both, if you are satisfied with a zwitterionic

Figure 1 The structures and shapes of carbon-based radicals.

Scheme 1 Resonance forms for allyl and alkoxymethylene radicals.

radical cation/anion pair as a resonance contributor (Scheme 1).

The stabilization of radicals by electronic effects reaches a somewhat unexpected peak in so-called *captodative* radicals,¹ where both electron releasing and electron withdrawing groups are attached to the same carbon radical center. The combined radical stabilizing effect of the two groups is significantly higher than additive.

Steric effects are also an important factor in radical stability but, when it comes to explaining the

origin of radical longevity/unreactivity, it is often difficult to tease apart a steric effect from an electronic one. The case in point is triphenylmethyl, Gomberg's first carbon radical (see **The History of Free Radical Chemistry**). The species exists in equilibrium at ambient temperature with its unsymmetrical dimer (Scheme 2). *A priori*, one might draw the planar structure of triphenylmethyl and think of electron delocalization as the origin of radical stability. Triphenylmethyl has a propeller shape, however, and the origin of its stability is primarily a steric effect: it is too sterically hindered to undergo coupling to form hexaphenylethane. In fact, coupling necessitates a dearomatization of one of the aromatic rings of the triphenylmethyl radical. Presumably, this contributes to the reluctance of triphenylmethyl to undergo self-reaction. Incidentally, Gomberg proposed the unsymmetrical dimer structure correctly in 1904. Nevertheless, the incorrect hexaphenylethane structure was widely accepted as the product of radical dimerization of triphenylmethyl until 1968.²

As we will see, it is most often the case that a radical will react very rapidly indeed with another radical. Those that do not undergo fast self-reaction are termed *persistent radicals*.³ Persistent radicals (Figure 2) may still undergo reaction with other radicals or triplet oxygen. Their persistence is often due to a combination of electronic stabilization and steric hindrance toward recombination and the lack of a β -H, which is needed for disproportionation.

The stability of a radical $R^\bullet$ (see **Radical Stability—Thermochemical Aspects**) can be estimated from consideration of the bond dissociation energy (BDE) of the corresponding $R-H$ compound (Figure 3). The lower the BDE, the weaker the

Scheme 2 Dimerization of the triphenylmethyl radical.

Figure 2 Examples of persistent radicals.

Figure 3 Radical stability and the relationship with bond dissociation energy (BDE).

bond and hence the more stable the radical. At first sight, the significant difference in strengths of C–H bonds (and O–H bonds) comes as a surprise: an aryl C–H bond strength is almost 100 kJ mol^{-1} stronger than a benzyl C–H bond, for example. Evidently, these bond strengths/stabilities have a significant influence upon chemical reactivity and the ability to set up an effective chain reaction. We will now look at radical chain reactions in more detail, and the discrete processes of which they are comprised.

1.2 Introduction to Chain Reactions and Discrete Radical Processes

Apart from a relatively small number of examples that are strongly stabilized through steric and electronic effects, radicals are typically promiscuous

species. In fact, most radicals react with one another at rates approaching the diffusion controlled limit. If essentially all collisions lead to productive bond formation, then it is inevitable that reactions involving radical–radical unions are going to be unselective. The development of modern chain reactions—made possible through fundamental physical organic chemistry studies (see **Radical Kinetics and Clocks**)—was the breakthrough that enabled selectivity in transformations involving radicals. As we will see, transformations of incredible intricacy and selectivity can be achieved through radical chain processes.

The mechanisms of radical chain reactions (Scheme 3) can be conveniently broken down into two stages: *initiation* (see **Overview of Radical Initiation**), which involves the formation of a few radicals to get things going and a *propagation cycle*, which is the business end of the reaction and involves the conversion of the precursor into

Scheme 3 A generalized radical chain mechanism.

the product. Both initiation and propagation stages of a radical chain reaction can involve several discrete mechanistic steps. *Chain termination* involves the consumption of radicals and is undesirable. Synthetically useful radical chain reactions require only small amounts of initiator, have efficient propagation steps, and minimize termination events.

The majority of radical reactions involve the stringing together of a surprisingly small number of different classes of discrete, concerted events (Scheme 4). This subsection serves as a general introduction to these different events. We will examine them in more detail in subsequent subsections.

Radicals are generated through *homolysis* processes. In its simplest form, homolysis involves the scission of a weak σ bond and is brought about by delivering a sufficient amount of energy to the substrate to break the bond. All covalent bonds will break homolytically if heated to high enough temperatures but for most synthetic purposes, an initiator with a covalent bond of BDE

$<200 \text{ kJ mol}^{-1}$ is employed. Halogens, dialkyl-, and diacyl-peroxides are examples of such compounds, which undergo homolysis to form halogen atoms, alkoxy, and acyloxy radicals, respectively (Scheme 5). Dialkyl-azo compounds are especially important in radical chemistry: these compounds undergo a double homolysis, generating two alkyl radicals and a molecule of nitrogen.

The initiation phase of radical chain reactions (see **Overview of Radical Initiation**) often involves a homolysis step, although there are many exceptions. For example, the reaction between Et_3B and oxygen can be used to generate ethyl radicals at low temperature (i.e., -78°C).⁴ Reactive organohalides can be converted into carbon-centered radicals by halogen abstraction by metals and their complexes (see **Transition Metals and Radicals**). One electron oxidation or reduction (see **Redox Properties of Radicals**), radiation (see **Radiation-Induced Radical Reactions**), and photolytic methods (see **Photo Induced Radical Reactions**) can also initiate radical chain reactions through mechanisms that do not involve the direct homolytic cleavage of a weak covalent bond.

Radical substitution, addition, and β -elimination processes are the three most common processes in the propagation phase of radical reactions (Scheme 6). They are well suited to chain reactions for the simple reason that they lead to a change in bonding while transmitting radical character from one species to another.

Unlike *nucleophilic* substitution processes, which readily occur through either dissociative ($\text{S}_{\text{N}}1$) or concerted ligand replacement ($\text{S}_{\text{N}}2$) mechanisms at

Scheme 4 The most common single step (i.e., concerted) radical events. The arrows colored blue are sometimes omitted.

Scheme 5 A selection of common radical initiators that undergo homolysis on exposure to heat or light.

β -Elimination is the reverse of addition...

Scheme 6 Simple examples of radical substitution, addition, and β -elimination.

carbon, direct radical substitution at carbon is a rare event. In contrast, radical substitution at the halogen atom of a C–X bond and the hydrogen of a C–H bond, both of which lead to carbon-centered radicals, are rather common. The concerted homolytic substitution mechanism, which operates in these and many other cases, bears the descriptor S_H2 (substitution, homolytic, bimolecular) (see **Intramolecular**

Homolytic Substitutions in Synthesis). Examples of common types of bonds broken in S_H2 processes (Scheme 6) are the relatively weak X–X, C–X, C–H, and Sn–H bonds. Those that are commonly formed are relatively strong O–H, C–H, and Sn–X bonds.

Radical additions (Scheme 6) are perhaps the single most important radical process, at least if

Scheme 7 Radical coupling steps witnessed in chain reactions.

judged in terms of synthetic application. Radicals add readily to many types of π bonds (see **Unusual Radical Acceptors**) and, in thermodynamic terms, the driving force for the process is the formation of a stronger σ bond at the expense of a weaker π bond. Steric, electronic, strain, and geometrical/conformational factors all impact upon the ease with which a radical and alkene react. β -Elimination is the reverse of addition and, in the absence of other factors listed in the preceding sentences, the position of the equilibrium is determined by the stabilities of the species (radicals and π bonds) involved. Nevertheless, β -elimination can be promoted by higher temperatures (entropy driven) or can be brought about by the removal of a volatile by-product from the reaction, according to Le Chatelier's principle.

As mentioned earlier, coupling is the process by which most radical chain reactions terminate and, in such a situation, is undesirable. Effective chain reactions use only small amounts of initiator, which allows the concentration of radical species in solution to be kept low, thereby minimizing unwanted termination through radical coupling events. Nevertheless, a relatively small number of radical chain reactions involve coupling processes as an integral part of the propagation cycle. Autoxidation, for example, involves the union of carbon-centered radicals with triplet O_2 as a key step (Scheme 7); a process that is perhaps best thought of as a radical–radical coupling event.

Carbon monoxide reacts well with carbon-centered radicals to form acyl radicals.⁵ Again, this can be thought of as a radical coupling process (as an aside, the reverse reaction, α -elimination, which involves the loss of CO from an acyl radical and is a lot like homolysis, is also known). Finally, it must be noted that there are

several preparatively useful *non-chain* radical reactions that involve coupling processes. These include the *pinacol reaction* (see **Organic Synthesis Using Samarium Diiodide**), the *McMurry reaction*, and the *acyloin condensation*.

While the five fundamental processes depicted in Scheme 4 form the basis of the majority of radical chain reactions, this collection is not exhaustive. Electron transfer processes are also important (see **Organic Electron Donors** and **The $S_{RN}1$ Reaction**), as are disproportion events. Certain rearrangements involving radicals involve concerted mechanisms, too (see **Radical Rearrangements: Ester-Substituted Radicals and Hydrogen Atom Migrations**).

We will complete this subsection with a look at a specific example of a simple radical chain reaction, which will bring together many of the concepts from the first two subsections of this article. The selected example is a *Kharasch reaction*, first reported in the mid-1940s.⁶ This chain reaction involves the overall addition of a C–Cl bond of CCl_4 across an alkene (Scheme 8).

Diacetyl peroxide serves as an initiator in these reactions, which undergoes homolysis to form acyloxy radicals that, in turn, undergo β -elimination to form methyl radicals. These reactive species abstract a chlorine atom from CCl_4 to generate $Cl_3C\cdot$ and chloromethane. This completes the initiation phase of the mechanism. The propagation cycle involves, firstly, an intermolecular radical addition of $Cl_3C\cdot$ to the less substituted end of the alkene bond of 1-octene. This is a thermodynamically favored process due to the formation of a C–C σ bond at the expense of a C=C π bond. The resulting secondary alkyl radical participates in an intermolecular substitution event, abstracting a Cl atom from CCl_4 to form the product and a $Cl_3C\cdot$ radical. It is important to recognize that the purpose of the initiation phase of the mechanism is to generate a radical that is part of the propagation cycle.

A combination of any two radicals would represent a termination event and is thus undesired. Radical–radical coupling is kept to a minimum in this—and many other—radical chain reactions by using only a small amount of initiator, which leads to a very small concentration of radicals in solution. For the propagation cycle to be effective, the two different radicals involved must be selective in their reactivity. In the case of the trichloromethyl radical, this should not be an issue, since reaction

Scheme 8 The mechanism of a Kharasch reaction ($\text{R} = n\text{-hexyl}$).

with another CCl_4 molecule would be neither a productive nor a destructive process. In the case of the secondary alkyl radical, reaction with another 1-octene molecule would represent the first step in a telomerization process. Evidently, success in the Kharasch reaction hinges upon the secondary alkyl radical abstracting a chlorine atom, rather than adding to another alkene π bond. We will return to this important issue at a later stage. In the next subsection, we will delve deeper into the design of radical chain reactions through an examination of the different types of reagents (initiators, mediators, and catalysts) that are employed to bring them about.

1.3 Introduction to Radical Mediators

There are several different ways to subdivide the many different known radical chain reactions. Here, we will adopt an approach that involves a consideration of the reagents used to bring about the

conversion of the precursor(s) into the product(s). The need for a reagent known as an *initiator* to produce a radical that is part of the propagation cycle was discussed in the preceding subsection. Despite its employment in a sub-stoichiometric quantity, the initiator is rarely a *catalyst* in radical chain reactions, since virtually all initiators are irreversibly transformed into radicals, which are further converted into some other by-product. Some reactions (e.g., Kharasch reaction, Scheme 8) do not need additional reagents to transform precursor into product; the initiator reacts directly with a substrate to generate a radical that is a part of the propagation cycle. In many instances, however, an additional reagent called a *mediator* is needed. A radical mediator is a reagent that is intimately involved in the conversion of the precursor(s) but contributes only a hydrogen atom to the product.

The most celebrated—and infamous—radical mediator is tri-*n*-butyltin hydride (see **Tin Hydrides and Functional Group Transformations**).⁷ Despite its toxicity (a problem that is further

Scheme 9 Radical chain reductive dehalogenation of organohalides with Bu_3SnH as mediator.

aggravated by the difficulty associated with removing its residues from organic products), Bu_3SnH still enjoys widespread use in synthesis. It is cheap and easily synthesized. It functions through the intermediacy of $\text{Bu}_3\text{Sn}^\bullet$, readily generated from the stannane by H atom abstraction by an initiator-derived radical. Scheme 9 depicts the simplest possible iteration of its use, namely for the reductive dehalogenation of organohalides. In the propagation phase, the mediating $\text{Bu}_3\text{Sn}^\bullet$ radical abstracts a halogen atom from the organohalide to generate carbon-centered radical $\text{R}^\bullet$, which abstracts a hydrogen atom from Bu_3SnH to form the dehalogenated product and a $\text{Bu}_3\text{Sn}^\bullet$ radical, thereby completing the cycle.

As we will see in Section 2 of this article, the immense power of Bu_3SnH and related mediators in synthesis stems from the fact that they bring about the formation of carbon-centered radicals with high selectivity under extremely mild conditions. In reductive dehalogenations (Scheme 9), the initially formed carbon-centered radical $\text{R}^\bullet$ simply abstracts a H atom from the mediator. Many different reactions have been invented, however, from sequences of discrete processes involving these initially formed

carbon-centered radicals *before* the H atom abstraction step.

Other tri(organo)tin hydrides $\text{R}_3\text{Sn-H}$ have been used as radical chain mediators but all suffer from the same toxicity issue as Bu_3SnH . Several less toxic replacements for stannanes have been introduced, including various silanes (see **Silanes as Reducing Reagents in Radical Chemistry**), germanes, phosphanes (see **Main-Group Elements in Radical Chemistry**), and boranes (see **Boron in Radical Chemistry**) (Figure 4). Without a doubt, the most successful is tris(trimethylsilyl)silane, $(\text{Me}_3\text{Si})_3\text{Si-H}$,⁸ which functions in a very similar manner to Bu_3SnH in many scenarios. The success of $(\text{Me}_3\text{Si})_3\text{Si-H}$ can be traced to the BDE of the Si-H bond in this compound, which is similar to that of the Sn-H bond in Bu_3SnH . The only drawback with this reagent is the cost (it is relatively difficult to prepare). Other silane-based mediators have Si-H bonds that are too strong, which impacts negatively upon their ability to sustain an efficient radical chain reaction. This is also the problem with germanes $\text{R}_3\text{Ge-H}$ (which are also rather expensive) and P-H-based reagents (which are cheap).

Figure 4 A selection of common radical mediators.

The problem of toxicity of tributyltin compounds and the problems of removal of tributyltin residues has been addressed in a number of ways. Some of the more interesting, from a mechanistic perspective, involve the use of Bu_3SnH as *catalyst* along with a stoichiometric amount of a reducing agent to convert the Bu_3SnX by-product back into Bu_3SnH . Notable contributions in this area by Corey,⁹ Stork,¹⁰ and Fu¹¹ have been made.

1.4 Introduction to Atom Transfer and Group Transfer Processes

The mediators discussed in the preceding subsection are reducing agents and they tend to lead to a decrease in functional group content in the molecule since, overall, a functional group in the substrate is removed and the H from the mediating reagent is incorporated. By employing chain reactions involving *atom transfer* and *group*

Scheme 10 The first example of an atom transfer radical cyclization (ATRC).

transfer processes, transformations that retain functional group content in the product have been devised (see **Halogen and Chalcogen Transfer Chemistry**). These reactions have the additional advantage that they do not require a mediator.

There are many examples of atom transfer radical chain processes. We have already seen the Kharasch reaction (Scheme 8), the very first reported example of what is now known as atom transfer radical addition (ATRA). A non-reducing version of the mediator Bu_3SnH , namely $\text{Bu}_3\text{Sn-SnBu}_3$, was used as an initiator by Curran in the first example of atom transfer radical cyclization (ATRC) in 1986 (Scheme 10).¹² It should be noted that a sub-stoichiometric amount of hexabutylditin is employed in this reaction. The initiation phase of the reaction might involve homolysis of the Sn-Sn bond to generate two $\text{Bu}_3\text{Sn}^\bullet$ radicals, one of which abstracts an iodine atom from the precursor to generate a tertiary alkyl radical and tributyltin iodide. This completes the initiation phase of the reaction and tin-containing species take no further part. In fact, the propagation cycle involves two steps and only the precursor. The tertiary alkyl radical undergoes 5-*exo-dig* radical cyclization (explained later) to form an alkenyl radical, which abstracts iodine from the precursor. This iodine atom transfer process works in thermodynamic terms since, in addition to the overall replacement of a $\text{C}=\text{C}$ π bond by a stronger σ bond, the product has a significantly stronger C-I bond than does the precursor.

Moving on from atom transfer processes, another very important class of radical chain reactions involves a related process known as *group transfer*. Such processes involve the overall substitution (usually through a stepwise addition-elimination sequence) at a group (usually thiocarbonyl-containing) as key steps in a propagation cycle. We will examine representative examples of group transfer processes in the second half of Section 2 of this article.

2 RADICAL CHAIN REACTIONS IN SYNTHESIS

In Section 1, the basic aspects of radical chain reactions were introduced. In the second part of this tutorial review, we will examine some of the more

commonly encountered issues pertaining to reaction design in radical chain reactions. The approach taken is one based upon mechanistic analyses of synthetic case studies and is divided into two sections: the first covers chain reactions that are sustained by reductive mediators and the second describes non-reductive processes. The literature coverage is by no means exhaustive. Furthermore, of the topics that are covered in this subsection, more detailed surveys are often provided in separate articles of this encyclopedia.

2.1 Radical Chain Reactions Employing Reductive Mediators

This subsection covers the major reaction classes that employ reductive mediators, namely, functional group removals, *intermolecular* radical additions, radical cyclization reactions, and related processes.

2.1.1 Reductive Removal of Functional Groups

Reductive radical mediators such as Bu_3SnH were introduced in Section 1 of this article. We saw that a $\text{Bu}_3\text{Sn}^\bullet$ radical, easily formed through initiation processes, readily generates a carbon-centered radical through halogen atom abstraction from an organohalide. This carbon-centered radical then abstracts a hydrogen atom from a Bu_3SnH molecule to complete the propagation cycle (Scheme 9).

Bu_3SnH has an almost ideal reactivity profile as a mediator, since it has an excellent balance of high chemoselectivity and broad substrate scope. A selection of the many possibilities for carbon-centered radical generation (and the reductive removal of functional groups) using mediators such as Bu_3SnH is shown in Scheme 11 (see **Tin Hydrides and Functional Group Transformations**). Thus, in addition to undergoing an $\text{S}_\text{H}2$ reaction at the halogen of an organohalide (Scheme 9), $\text{Bu}_3\text{Sn}^\bullet$ will also undergo radical substitution at the sulfur of sulfides (PhS groups are popular) and the selenium of selenides (phenyl selenides are most frequently used) to generate carbon-centered radicals. Some nitro-compounds and isonitriles also yield carbon-centered radicals on reaction with $\text{Bu}_3\text{Sn}^\bullet$,

Scheme 11 A selection of the many functional group removals that can be brought about by Bu_3SnH and related mediators.

in reactions that involve addition/elimination mechanisms to obtain overall substitution by Bu_3SnH at the functional group. Even alcohols and carboxylic acids serve as precursors to carbon radicals through *Barton–McCombie deoxygenation*^{13,14} and *Barton decarboxylation*.^{15,16} In the latter case, the process occurs with loss of one carbon.

The alcohol or carboxylic acid precursor is converted into a derivative containing a thiocarbonyl group through an esterification-type process; it is the thionocarbonyl derivative that is used in a reaction with Bu_3SnH (or other mediator). In Barton–McCombie deoxygenation (Scheme 12), commonly encountered thiocarbonyl derivatives are xanthates, thionoureas and, particularly, aryl thionocarbonates. The Bu_3SnH radical adds to the

thiocarbonyl group in the first step of the propagation cycle. The resulting adduct radical undergoes β -elimination to form the carbon-centered radical and a carbonyl-containing by-product, and then hydrogen atom delivery to $\text{R}^\bullet$ by the mediator completes the propagation cycle in the usual manner. This reaction tends to work best for deoxygenation of secondary alcohols. With primary alcohol derivatives, higher temperatures are generally needed to increase the rate of the β -elimination step, which is less favored when $\text{R}^\bullet$ is a primary alkyl radical. The deoxygenation of thionocarbonate derivatives of tertiary alcohols can be complicated by a competing pericyclic (Chugaev) elimination process.

The Barton decarboxylation sequence (Scheme 13) is similar, in that it also involves a

Scheme 12 Barton–McCombie deoxygenation of alcohols.

Scheme 13 Barton decarboxylation.

non-radical esterification-type process to form the substrate for the radical reaction. The substrate is an *O*-acyl thiohydroxamate derivative, which undergoes addition at the sulfur of the thiocarbonyl group by the mediating radical (thiols have also been used). A sequence of two β -elimination steps gives the carbon-centered radical, which collects a hydrogen atom from the mediator to complete the propagation cycle. The overall transformation for the two steps is $\text{R-CO}_2\text{H} \rightarrow \text{R-H}$, with the carbon lost as CO_2 . The thermodynamic driving force for this reaction comes from the aromatization of the heterocyclic ring of the *O*-acyl thiohydroxamate precursor and the replacement of the weaker $\text{C}=\text{S}$ bond with the stronger $\text{C}=\text{O}$ bond.

Of course, it is not necessary for a carbon-centered radical formed in one of these reactions to complete the propagation cycle directly; instead, the formation of $\text{R}^\bullet$ can serve as a starting point for other sequences of bond-forming and -breaking events before finally collecting a H atom from the mediator. Furthermore, we shall see in a later subsection that *O*-acyl thiohydroxamates and *S*-xanthates have been employed with great effect in group transfer chain reactions, processes that do not mandate the presence of a mediator.

One of the more intriguing aspects of radical reactions is that they are influenced by polar effects. The Si-H BDE in $\text{Et}_3\text{Si-H}$ is 398 kJ mol^{-1} , which is significantly higher than that of the Sn-H bond

Scheme 14 A reasonable-looking propagation cycle for the reductive dehalogenation of organohalides by Et_3SiH .

in Bu_3SnH (308 kJ mol^{-1}) and the Si-H bond in $(\text{Me}_3\text{Si})_3\text{Si-H}$ (351 kJ mol^{-1}). Nevertheless, the $\text{Et}_3\text{Si-H}$ bond strength is still lower than that of most C-H bonds (Figure 3), so the sequence shown in Scheme 14 should be a reasonably effective propagation cycle for the reduction of most organohalides (see **Silanes as Reducing Reagents in Radical Chemistry**).

Experimentally, these chain reactions are rarely synthetically useful since the second step is too slow at usual working temperatures. The problem is that alkyl radicals are nucleophilic species and the silane is an electron-rich source of hydrogen atoms, hence the reaction has unfavorable polar characteristics. Of course, $(\text{Me}_3\text{Si})_3\text{SiH}$ and Bu_3SnH also suffer the same problem but presumably, the significantly weaker Si-H (Sn-H) bond strengths in these mediators compensate somewhat. The solution with Et_3SiH , cleverly developed by Roberts, involves the addition of a catalytic amount of a hydrogen atom donor that reacts rapidly with alkyl radicals. A thiol serves as a *protic polarity reversal catalyst* in this

Scheme 15 Polarity reversal catalysis in the reductive dehalogenation of organohalides by Et_3SiH .

reaction and replaces the one slow step with two fast ones, substitutions that benefit from favorable polar effects (Scheme 15).¹⁷

This is only one example of the many effective *polarity reversal catalysis* processes in radical reactions that have been developed by Roberts.¹⁸ As we will see, polar effects are a general feature of radical reactions.

2.1.2 Intermolecular Radical Additions to Multiple Bonds

The Kharasch reaction (Scheme 8) and more modern metal-catalyzed variants (Section 2.2) form a new C–C bond through an intermolecular addition of a carbon-centered radical to an alkene. In the process, a new C–X bond is also forged. A reductive variant of this process was developed by Bernd Giese.¹⁹ *Giese reactions* involve the union of organohalides and alkenes, are mediated by Bu_3SnH (or similar), and are of broader scope than Kharasch reactions. A generalized reaction is depicted in Scheme 16. The mechanism is essentially identical to radical reductive dehalogenation, except that an intermolecular radical addition step occurs after the abstraction of the halogen atom by $\text{Bu}_3\text{Sn}\cdot$ and before the transfer of a hydrogen atom to the carbon-centered radical by Bu_3SnH .

To optimize the yield of the addition product, some planning is usually needed with respect to how these chain reactions are conducted in the laboratory, specifically with respect to the relative concentrations of organohalide, alkene, and tributyltin hydride. A fine balance is needed here, since too high a concentration of Bu_3SnH will lead to premature trapping of the initially formed carbon-centered radical ($\text{R}\cdot$ in Scheme 16) and formation of the direct reduction product of the organohalide. Conversely, the concentration of the alkene must be kept high to favor the addition step. This is achieved through the slow addition of Bu_3SnH (and a small amount of initiator such as AIBN) to a concentrated solution of alkene (usually in excess) and organohalide in a non-H atom donor solvent (cyclohexane and benzene are commonly used).

It turns out that the rate of the addition step—and the success of these intermolecular radical addition reactions—is strongly dependent upon the nature of both the alkene and the organohalide. The fastest reactions occur between *either* electron-rich (nucleophilic) radicals and electron-deficient (electrophilic) alkenes *or* electrophilic radicals and nucleophilic alkenes. These polar effects are best explained by consideration of the frontier molecular orbitals (FMOs) of the radical and the alkene components (Figure 5).

Scheme 16 Intermolecular reductive radical addition to C=C bonds: the Giese reaction.

Figure 5 FMO interactions in radical additions to alkenes.

The radical SOMO (singularly occupied molecular orbital) is expected to reside between the energies of a π bond HOMO (highest occupied molecular orbital) and LUMO (lowest unoccupied molecular orbital). With the electron-rich radical (high lying SOMO)/electron poor alkene (low lying HOMO and LUMO) pairing, the dominant FMO interaction is between the radical SOMO and alkene LUMO. With an electrophilic radical and electron-rich alkene, the SOMO(radical)–HOMO(alkene) FMO interaction dominates. Despite an electron being placed in an anti-bonding orbital, this latter mixing of MOs still leads to a net energy gain.

Polar effects explain many aspects of radical reactions. In the Kharasch reaction (Scheme 8), for example, the trichloromethyl radical (an electrophilic radical) adds to 1-octene (an electron rich olefin). The resulting alkyl radical is nucleophilic,

hence its propensity for addition to 1-octene is lower, and the reaction can be stopped at the mono-addition stage. Evidently, such factors are of paramount importance in both synthetic organic chemistry and polymer chemistry.

An ingenious variation on the theme of intermolecular radical addition reactions involves the radical chain allylation of organohalides. *Keck allylation* (Scheme 17) employs allyltributyltin as the alkene component.²⁰ Following addition of the organohalide-derived carbon radical to the less substituted end of the alkene, β -elimination ensues, resulting in the formation of the allylated product and a $\text{Bu}_3\text{Sn}^\bullet$ radical, which completes the propagation cycle. Thus, *overall* radical substitution occurs through a stepwise addition/ β -elimination sequence, since the alkene carries a “radical leaving group” substituent (Bu_3Sn) at the allylic site.

Scheme 17 Intermolecular radical allylation: the Keck reaction.

The importance of intermolecular additions in the development of modern synthetic radical chemistry cannot be overstated. It is fair to say, however, that the biggest impact of this work was in its extension to *intramolecular* additions. In total synthesis, radical cyclization technology is a widely used synthetic tool of broad application.

2.1.3 Intramolecular Radical Additions to Multiple Bonds

When a radical center and a π bond are connected by a tethering chain, intramolecular addition is possible and two distinct cyclization modes can ensue (Scheme 18). These two modes involve either formation of a bond to the more proximate atom in the chain, in which case, the radical will end up outside of the ring (*exo* mode). Alternatively, formation of a new σ bond to the more distant atom of the π bond results in the radical ending up inside of the ring (*endo* mode).

More generally, radical cyclizations are classified by *Baldwin's rules of ring closure*, which take into consideration the ring size formed, whether the

mode is *exo* or *endo*, and the type of center to which the bond is formed (tetrahedral, trigonal planar, or digonal).²¹ These empirical rules, which are not solely applicable to radical cyclizations, were based upon analysis of conformational features impacting upon orbital overlap during cyclization reactions, and led to a classification of cyclization types as *favored* or *disfavored*. Baldwin's rules will not be discussed in detail here but for our purposes, it is important to note that 5-*endo-trig* radical cyclizations in all-carbon systems are *disfavored* (see **Unusual Cyclizations**).

One of the classic examples of radical cyclization reactions involves the 5-hexenyl radical, a species that can be conveniently generated through halogen atom abstraction from the halide by $\text{Bu}_3\text{Sn}^\bullet$ (Scheme 19).²² Under kinetically controlled conditions, the major product of the Bu_3SnH -mediated process is methyl cyclopentane, resulting from a 5-*exo-trig* radical cyclization. Cyclohexane, generated through the alternative 6-*endo-trig* mode of cyclization, is formed as a very minor product.

On face value, the preference for the *exo*-cyclization mode is unexpected for three reasons: both the five-membered ring and the

Scheme 18 Radical cyclization modes.

Scheme 19 Radical cyclization of 1-bromo-5-hexene through a Bu_3SnH -mediated chain reaction.

primary alkyl radical are less thermodynamically stable than the six-membered ring and the secondary alkyl radical, which result from the alternative *endo*-cyclization mode. Furthermore, addition to the less substituted end of the alkene (i.e., *endo*-mode addition) would be expected to have less steric impact. The preference for *exo*-mode of cyclization is explained by the need for good overlap between the SOMO and the orbitals associated with the alkene π -system. The angle of approach of a radical to a $\text{C}=\text{C}$ bond—calculated to be around 109° —is significantly better accommodated by the transition state leading to *exo*-mode cyclization.

The kinetic preference for the *5-exo-trig* mode of cyclization is quite general, with substrates containing heteroatoms in the chain also usually giving the smaller ring size. Substituted 5-hexenyl radicals also show a marked preference for the *exo*-mode of cyclization, with the exception of 1,1-disubstituted alkenes. In this case, steric strain destabilizes the transition state leading to the *5-exo-trig* product, thus the *6-endo-trig* product is mildly favored. The higher homolog, the 6-heptenyl radical, also preferentially undergoes an *exo*-mode cyclization, albeit with a slightly diminished selectivity relative to the lower homolog. Diastereoselectivity in reactions of substituted precursors is predictable on the basis of *Beckwith–Houk transition state models*,^{23,24} which consider chair- and boat-like transition states and a

preference for substituents to adopt equatorial orientations (see **Stereoselective Radical Reactions**). Polar effects still operate in intramolecular radical additions but their effects are less important than in intermolecular additions. Operationally, it is often advantageous to keep both the substrate concentration and Bu_3SnH concentration low during radical cyclization reactions, to minimize premature trapping of the uncyclized radical by H atom transfer from the mediator.

One rather obvious feature of a radical cyclization step is the formation of another radical. In a carefully designed precursor, this cyclized radical can participate in a second radical cyclization. Domino radical chain sequences are among the most powerful ways to rapidly generate complex structures (see **Radical Cascade Reactions**). An early example of a double radical cyclization is Curran's landmark synthesis of hirsutene, generally accepted as a classic in synthesis design and execution (Scheme 20).²⁵ In the propagation cycle, a $\text{Bu}_3\text{Sn}^\bullet$ radical abstracts the iodine atom from the monocyclic precursor, generating a primary alkyl radical. A *5-exo-trig* radical cyclization onto the cyclic alkene generates a bicyclic tertiary alkyl radical, which cyclizes in a *5-exo-dig* manner to generate a tricyclic alkenyl radical. Abstraction of a H atom from Bu_3SnH forms the natural product and completes the propagation cycle.

Scheme 20 Curran's domino radical cyclization approach to hirsutene.

Whereas the formation of five- and six-membered rings are the most common, radical cyclizations have been employed to form all ring sizes, from three-membered systems to macrocycles (see **Unusual Cyclizations**). Cyclizations to form three- and four-membered rings are generally fast and reversible, with the equilibrium usually favoring the ring opened form.

Radicals add intramolecularly to all manner of different π bonds. The reversible addition to the carbonyl bond of ketones, for example, forms the basis of the *Dowd–Beckwith ring expansion* protocol.^{26,27} Radicals will add intramolecularly to benzene rings, with new bonds being formed to either the ipso- or the ortho-positions (see **Radical Arylations**).

Finally in this subsection on chain reactions controlled by reductive mediators, we will consider a very useful process that is related to radical cyclizations (and is often followed by one). The process is an intramolecular radical substitution at hydrogen, which often proceeds through a six-membered transition state. This process was popularized through the *Barton reaction*,²⁸ a non-chain remote functionalization method famously applied to steroids. That intramolecular hydrogen atom transfers (HATs), as they are known, can be useful in reductive chain reactions and is demonstrated by the example shown in Scheme 21.²⁹

In this example, an alkenyl radical selectively abstracts the hydrogen atom from a tertiary

alkyl C–H bond, then cyclizes back onto the alkene. The alkenyl radical is generated through the addition of a thiyl radical to an alkyne precursor, which is usually an efficient process (see **Radical Thiol–X Click Chemistry**). The last step in the propagation cycle involves abstraction of the H atom of the thiol by the cyclized alkyl radical. Intramolecular HAT processes are extremely useful in synthesis. Alkenyl, aryl, and alkoxy radicals are the most frequently encountered abstracting species and alkyl C–H bonds are the ones usually suffering substitution.

2.2 Non-Reductive Radical Chain Reactions

In this final subsection of our article on fundamental aspects of chain reactions, we will look at some of the most notable radical chain processes that proceed *without* the assistance of a reductive mediator. These include autoxidation, radical halogenation, and atom and group transfer sequences.

2.2.1 Introduction of Functional Groups: Autoxidation and Radical Halogenation

One of the most important radical chain reactions is autoxidation. This rather poorly named process involves a radical chain reaction between an organic substrate and oxygen, and occurs for

Scheme 21 An example of a reductive chain reaction involving an intramolecular 1,5-hydrogen atom transfer (1,5-HAT).

Scheme 22 Autoxidation of diethyl ether.

all organic compounds (including biological ones) carrying relatively weak C–H bonds. The autoxidation of diethyl ether is provided as an example (Scheme 22).

The initiation phase of autoxidation is unclear, but ultimately involves the generation of a carbon-centered radical. In the case of diethyl ether, it is the more stable of two possible carbon-centered radicals. This radical then couples with triplet oxygen to form a hydroperoxyl radical, which, in the second and last step of the propagation cycle, abstracts a hydrogen atom from one of the weaker C–H bonds of the substrate. Once initiated, the autoxidation mechanism is usually very efficient,

with a relatively small number of radicals needed to transform large amounts of substrate. The autoxidation chain reaction can be disrupted by the addition of a better H atom donor than the substrate. Such compounds include substituted phenols such as BHT (2,6-di-*tert*-butyl-4-methylphenol) and toco-pherol. These antioxidants function by delivering a H atom to the hydroperoxyl radical involved in the propagation cycle (see **Antioxidants in Chemistry and Biology**).

Radical chain halogenations of alkanes are well-established reactions. One of the most useful is the *Wohl–Ziegler reaction*,³⁰ in which an allylic or benzylic C–H bond is replaced by a C–Br

Scheme 23 Allylic (benzylic) bromination with *N*-bromosuccinimide (NBS).

bond. The mechanism of this chain reaction is intriguing, since it involves an ionic process in the radical chain reaction. The reagent of choice is *N*-bromosuccinimide (NBS) (Scheme 23).

Following the initiation phase of the reaction, which involves the homolysis of the weak Br–Br bond (Br_2 is present as a minor contaminant in samples of NBS), the bromine radical abstracts a hydrogen from the weakest C–H bond in the molecule, which is the allylic one, thereby forming the allyl radical and HBr. The HBr reacts with NBS to form succinimide and Br_2 in an ionic reaction. The allyl radical then abstracts a bromine atom from Br_2 in the last step of the propagation cycle. In principle, Br_2 could be used as the reagent for this reaction (imagine the propagation cycle of Scheme 23 without the ionic step). In practice, the reaction with Br_2 would be thwarted by competing electrophilic additions of the reagent and the by-product, HBr. NBS is so effective in this reaction since it keeps the concentration of HBr and Br_2 very low, thereby minimizing unwanted electrophilic additions.

2.2.2 Atom and Group Transfer Radical Chain Reactions

Kharasch-type ATRA reactions (Scheme 8) were of enormous importance in the development of radical chemistry (see **Halogen and Chalcogen Transfer Chemistry** and **Atom Transfer Radical Polymerization (ATRP) and Addition (ATRA) and Applications**). Nevertheless, Kharasch reactions are of rather limited scope, since they are plagued by the problem of selectivity; specifically, the atom transfer step cannot adequately compete with intermolecular addition to another molecule of alkene, so telomerization sometimes occurs.

The problems of selectivity in classical Kharasch chain reactions has been addressed through the use of Cu, Ni, Fe, and Ru metal complexes as *catalysts* (in some cases, the metal in elemental form has been used) (see **Halogen and Chalcogen Transfer Chemistry**). The mechanisms of these reactions (Scheme 24) involve, firstly, the generation of a carbon-centered radical (e.g., $\cdot\text{CCl}_3$) from a reactive organohalide compound (e.g., CCl_4) by overall

Scheme 24 Possible mechanism of a metal-catalyzed ATRA reaction.

abstraction by the metal catalyst in its lower oxidation state (e.g., $\text{Cu}^{\text{I}}\text{L}_n$). The $\cdot\text{CCl}_3$ radical then undergoes addition to the alkene and the resulting adduct radical abstracts a halogen atom from the higher oxidation state metal complex, $\text{L}_n\text{Cu}^{\text{II}}\text{Cl}$. The catalytically active, lower oxidation state metal complex is thus regenerated and feeds back into the propagation cycle.

The metal complex-catalyzed chain reaction is more effective than the traditional Kharasch reaction since the higher oxidation state metal halide is a better halogen atom donor than the organohalide. Nevertheless, the scope of these reactions is once again limited by the nature of the halide precursor and product: generally speaking, the product must carry a significantly stronger C–X bond than that of the precursor.

Evidently, the adduct radical might go on to react with another alkene molecule, which in turn can add to another, and so on. This process, termed *atom transfer radical polymerization* (ATRP) (see **Atom Transfer Radical Polymerization (ATRP) and Addition (ATRA) and Applications**) has been used to great effect for the controlled preparation of polymeric materials. ATRP and ATRA are notable since they do not require a radical initiator. Nevertheless, it has been demonstrated recently that the addition of small amounts of AIBN improves the efficiency of these reactions with respect to the loading of the metal complex. It is believed that

the AIBN assists by forming a steady stream of carbon radicals, which abstract chlorine from the higher oxidation state metal catalyst, thus reducing it to the catalytically active form.³¹

As the name suggests, *group* transfer radical reactions are related to their atom transfer counterparts in that a group, rather than an atom, is relocated during the chain reaction. Chalcogen “pseudohalides” (e.g., SPh, SePh) have been employed in this manner, in which case, the transfer step is analogous to that with the halide (see **Halogen and Chalcogen Transfer Chemistry**). Different types of group transfer radical reactions are possible, however, with relocatable groups carrying a thiocarbonyl bond. *O*-Acyl thiohydroxamates and *S*-xanthates are useful functionalities in this regard.

The chemistry of *O*-acyl thiohydroxamates, or *Barton esters*, is rich and varied. Earlier in this article, the decarboxylation of carboxylic acids through the treatment of Barton esters with a reductive mediator was discussed. Replacement of the H atom donor with CCl_4 gives rise to a mild and general alternative to the classical Hunsdiecker reaction.³² Intermolecular additions to alkenes are also feasible, as demonstrated by the reaction with *para*-benzoquinone,³³ depicted in Scheme 25.

In the initiation phase, Barton esters undergo heat or light-mediated fragmentation to the alkyl

Scheme 25 Group transfer radical chain reaction involving an *O*-acyl thiohydroxamate.

radical $R^\bullet$. In the propagation phase, intermolecular addition of $R^\bullet$ to the benzoquinone gives the adduct radical, which then adds to another molecule of the Barton ester. Aromatization–fragmentation to the acyloxy radical followed by decarboxylation gives the product, a dihydroquinone, which is oxidized to the quinone, presumably through tautomerization to the hydroquinone and then oxidation. The by-product in this last β -elimination step is the alkyl radical $R^\bullet$, which completes the propagation cycle.

Zard has employed *S*-xanthates (not to be confused with *O*-xanthates, the derivatives used in the Barton–McCombie reaction) in imaginative ways (see **Xanthates and Related Derivatives as Radical Precursors**). Scheme 26 depicts a representative example from the Zard group, involving a domino radical addition approach to the alkaloid natural product matrine.³⁴ This final example involves the union of two monocyclic building blocks to form the tetracyclic framework of the natural product in

one step. The diacyl peroxide initiator breaks down through successive homolysis and β -elimination of CO_2 to form alkyl radicals $R^\bullet$. These add to the thio-carbonyl sulfur atom to generate the adduct radical, which breaks down through β -elimination to give the first radical of the propagation cycle, an α -acyl carbon radical species. In the propagation cycle, intermolecular addition of the α -acyl carbon radical to the monosubstituted alkene generates a secondary alkyl radical. Two successive 6-*exo-trig* radical cyclizations give the tetracyclic radical. Intermolecular addition to the *S*-xanthate precursor followed by β -elimination gives the final product and another α -acyl carbon radical by-product, thereby completing the propagation cycle.

Three new C–C bonds and five contiguous stereocenters are formed in this remarkable transformation, which showcases the synthetic power not only of group transfer radical reactions but of free radical chain reactions in general.

Scheme 26 *S*-Xanthate group transfer domino radical chain reaction by Zard ($R = C_{11}H_{23}$).

3 CONCLUSIONS

A chain reaction involves a sequence of events that generates a product or by-product that serves as a substrate for a further reaction. While relatively uncommon in cationic and anionic chemistry, chain

reactions are the principal method in radical chemistry. A chain reaction channels the high chemical reactivity of radicals and permits highly selective chemical transformations, not only in chemical synthesis but also in material applications and biological scenarios.

Intramolecular Homolytic Substitutions in Synthesis

Sara H. Kyne and Carl H. Schiesser

School of Chemistry and Bio21 Molecular Science and Biotechnology Institute, The University of Melbourne, Victoria, Australia

1 INTRODUCTION

Free radical chemistry contributes to the modern chemists' toolbox in ways that were unimaginable only a few decades ago. There can be no doubt that the construction of carbocyclic and heterocyclic ring systems through the intramolecular addition of alkyl, aryl, and other radicals to unsaturated functionalities is a major contribution to synthetic methodology; this chemistry is the topic of other contributions to this collective work. It is important to recognize that the fundamental principles that guide the use of intramolecular homolytic addition chemistry in synthesis, eloquently summarized by Giese in his 1986 monograph,¹ also apply to intramolecular homolytic substitution chemistry. It was recognized some time ago that most organic free radical addition reactions are under kinetic control and this means that an understanding of fundamental rate and mechanistic data are crucial in designing useful chemical reactions based on these free radical processes¹; the same holds true for reactions involving homolytic substitution chemistry.

Intramolecular homolytic substitution chemistry for the construction of heterocycles was in its infancy as recently as 20 years ago, having largely been used for constructing sulfur-containing ring systems. One of us contributed to a comprehensive review on homolytic substitution chemistry some 15

years ago,² and more recently, presented a feature article,³ while other reviews have been written on the topic since then.^{4,5} The purpose of this article is to provide a practical guide to intramolecular homolytic substitution chemistry, focusing primarily on chemistry developed over the past decade. It is intended to deliver a cross-section of information of relevance to the synthetic practitioner as well as to provide relevant experimental procedures. It is deliberately not meant to be comprehensive, but rather, through examples, intended to provide useful information about the state-of-play of radical substitution chemistry, and what is possible using this relatively new addition to the chemists' toolbox.

2 FUNDAMENTAL PRINCIPLES

To fully appreciate the scope and limitations of homolytic substitution processes at higher heteroatoms, one needs to appreciate the mechanisms by which these reactions proceed, and their associated rate constants. It has been generally agreed that three mechanisms exist for these reactions (Scheme 1).² These include a backside mechanism similar to S_N2 , leading to Walden inversion, as well as a frontside mechanism that would result in retention of configuration at asymmetric heteroatoms such as silicon, germanium, or tin. The third possibility involves a hypervalent

Scheme 1 Inter- versus intramolecular homolytic substitution at main group higher heteroatoms.

intermediate that may or may not undergo pseudorotation before dissociation, possibly resulting in racemization when the heteroatom undergoing attack is stereogenic.

Homolytic group (and atom) transfer reactions can involve either inter- or intramolecular homolytic substitution processes. Scheme 1 summarizes the trends observed for these reactions, and these trends provide useful information in relation to cyclization reactions at main group higher heteroatoms. The data provided in Scheme 1 indicate that intermolecular group transfer reactions have been reported for hydrogen, as well as for most of the main group elements. However, the analogous intramolecular process is only observed for hydrogen, silicon, germanium, and tin. To the best of our knowledge, there are no reported examples of intramolecular homolytic substitution at the pnictogens (N, P, As); however, several intermolecular examples exist.⁶

These observations raise obvious questions such as why do group 14 elements undergo this intramolecular chemistry while there are no reported examples for the chalcogens and halogens? Computational chemistry as well as carefully constructed experiments have shed light on the underlying reasons for the trends observed for these group transfer reactions.^{7–12}

Other than the substitution at hydrogen, which would appear to “go around corners” because of the orbitals involved during homolytic substitution, for the remaining main group elements, the backside mechanism requires a collinear (or nearly so) arrangement of attacking and leaving radicals with deviations from this geometry resulting in unfavorable processes with high-energy transition states. For example, Wild showed that 1,4-, 1,5-, and 1,6-homolytic translocations of chlorine, bromine, and iodine have prohibitively high-energy barriers as determined by MP2/DZP calculations (Scheme 2) consistent with substantially “bent” transition state geometries at the halogen (120–145° for 1,5-translocations).⁷ Wild also determined the angular dependence of the MP2/DZP calculated energy for the transition state (**1**) involved in the degenerate reaction of methyl radical with chloromethane. As the angle (θ) is reduced from 180° (ideal) there is a continual rise in transition state energy to a maximum at 90° at which point the transition state has suffered an increase in energy of about 112 kJ mol⁻¹.⁷ While there was a 3.4 kJ mol⁻¹ decrease in progressing to 80°, no saddle point for a frontside mechanism was located. It is clear from this study that homolytic substitution at halogen has a strong preference for backside attack in which the attacking and leaving radicals adopt a collinear arrangement.⁷

Similar observations are made for translocation reactions involving chalcogen. Computational studies suggest that group transfer processes

Scheme 2 Dependence of geometry on homolytic halogen translocation reactions.

Scheme 3 Some calculated homolytic ring closures at sulfur, selenium, and tellurium.

involving homolytic substitution at sulfur and selenium proceed through a backside mechanism and, as was predicted for halogen, have prohibitively high energy barriers, once again the result of significant deviations from the ideal geometry for backside attack at these heteroatoms.⁸ MP2/DZP calculations provide energy barriers in the 90–140 kJ mol⁻¹ range for 1,5-, 1,6-, and 1,7-chalcogen transfer, depending on the heteroatom. However, unlike halogen, Wild was able to locate a second transition state for intramolecular homolytic substitution at sulfur and selenium, and that transition state led to the formation of the corresponding heterocycle.⁸ Indeed, so unfavorable is intramolecular translocation at sulfur and selenium that even a hydrogen atom is calculated to prefer to leave, resulting in the formation of the heterocycle in preference to group transfer (Scheme 3)! So, here we have a fundamental difference between chalcogen and halogen: the second substituent on the chalcogen can act as a leaving group; indeed, it would appear to be easier to adopt the required “backside attack” orientation of attacking and leaving radicals during ring formation, than during translocation.

The story is slightly more complicated for reactions involving tellurium in that radical attack at

tellurium mostly results in the formation of hypervalent intermediates; however, they are calculated to lie in very shallow wells on their respective potential energy surface and, as a consequence, behave in a similar manner to their sulfur and selenium counterparts in relation to the overall chemistry observed (Scheme 3).⁸

Given these computational data, one might begin to imagine ways of engineering systems that would result in efficient ring formation and it is no surprise that many synthetically useful examples of this chemistry are carried out using stable radical leaving groups such as *tert*-butyl and benzyl.

So, what about silicon, germanium, and tin? Computational and mechanistic studies have revealed that homolytic substitution at these heteroatoms can proceed by using either frontside or backside substitution mechanisms, with both pathways often in competition with each other.⁹ For example, the degenerate reaction of silyl radical with disilane is calculated to have CCSD(T)/aug-cc-pVDZ//MP2/aug-cc-pVDZ energy barriers of 52.7 and 58.2 kJ mol⁻¹ for the frontside and backside pathways, respectively (Scheme 4).⁹ Similar results have been obtained for other systems.^{10,13} Clearly, unlike the chalcogens

Scheme 4 Backside versus frontside mechanisms in the homolytic substitution of silyl radical at disilane.

Scheme 5 Example of a 1,5-translocation involving an asymmetric silicon substituent.

and halogens, this chemistry at the group 14 higher heteroatoms does not require collinear arrangements of attacking and leaving radical, and the (approximately) 80° requirement for the frontside transition state is convenient for group transfer chemistry.

These computational studies were nicely complemented by the work of Horvat who showed that homolytic translocation involving a stereogenic silicon atom proceeds with retention of configuration, consistent with the involvement of a frontside transition state (Scheme 5).¹¹

To summarize this section, homolytic substitution at the chalcogens and halogens proceeds via backside mechanisms that involve transition states

in which the attacking and leaving radicals prefer to adopt a collinear (or nearly so) arrangement. This requirement introduces prohibitive amounts of strain in the transition states for 1,*n*-translocation reactions. However, it can be harnessed to generate chalcogen-containing ring systems that include molecules such as tetrahydroselenophene. In the case of elements such as silicon, germanium, and tin, this chemistry can proceed via frontside or backside mechanisms leading to translocation and cyclization possibilities. Examples of these chemistries are provided below.

3 INTRAMOLECULAR HOMOLYTIC SUBSTITUTION AT THE CHALCOGENS

3.1 Kinetic Data for Ring-Closure Reactions

Unlike intramolecular homolytic addition chemistry that abounds with useful rate data for the synthetic practitioner to use in crafting the optimum conditions for their reactions of interest (see **Radical Kinetics and Clocks**), fewer rate data are available for ring-closure reactions involving radical attack at higher heteroatoms. As mentioned earlier, because radical reactions are usually under kinetic control, the availability of rate constants for key (model) reactions is crucial for their success in the laboratory. For that reason, we have decided to include the available kinetic data for ring closure at sulfur, selenium, and tellurium in this article (Table 1). While most of the data for sulfur were reported in the 1996 review,² or in the more recent compilation by Crich,⁵ rate constants for these reactions at selenium and tellurium have never been reported together before; their inclusion here provides valuable insight into intramolecular homolytic substitution involving these elements.

The data presented in Table 1 clearly show that rate constants for homolytic substitution at the chalcogens depend on three key factors: (i) the nature of the heteroatom, (ii) the size of the ring being formed, and (iii) the stability of the leaving group. Keeping ring size and leaving radical the same, in progressing down the group from sulfur to selenium and tellurium, there are significant increases in rate constant; from sulfur to selenium this increase is often 2 to 3 orders of magnitude, with a similar change observed in progressing from

Table 1 Representative rate constant data at 80 °C for homolytic ring closures of sulfides, selenides, and tellurides.

selenium to tellurium, although there is only one example of the latter in the list. This trend is attributable to the size of the orbitals involved in the substitution process, with the larger orbitals provided by selenium and tellurium clearly preferred by the attacking radical to those offered by sulfur.

The choice of leaving group is also critical, although this can be somewhat negated by the heteroatom undergoing substitution, as discussed above. The usual reactivity order is observed with $1^\circ < 2^\circ < 3^\circ < \text{Bz} < \text{Bn} < \text{Ph}_2\text{C} < \text{RS}$. It is interesting to note that judicious choice of leaving group can turn a poor reaction (e.g., Entry 3) into an excellent reaction (e.g., Entry 10) and this should be kept in mind when designing synthesis based on this chemistry.

In a similar manner to that observed for intramolecular homolytic addition chemistry, and

for similar reasons, the size of the ring being formed has an influence on the rate constant because it affects the energy of the transition state involved in ring closure. Five-membered transition states are most favorable because the required collinear arrangement of attacking and leaving radicals is more easily accommodated with four bridging atoms than with the five involved in the formation of the analogous six-membered ring.⁸ As can be seen from the data in Table 1, six-membered rings are often formed 1 to 2 orders of magnitude more slowly than their five-membered counterparts.

Despite providing guidance, the data in Table 1 do not provide any information about competing side-reactions. The most common side-reaction is 1,*n*-hydrogen transfer from the “leaving group” to the incoming radical, an example of which is provided in Scheme 6.¹⁵ Benzylic leaving groups

Scheme 6 Hydrogen transfer often competes with homolytic substitution at sulfur.

Scheme 7 An example of homolytic ring closure at sulfur with an aryl leaving group.

on sulfur are not suitable for this chemistry; the relatively slow homolytic substitution process at sulfur provides excellent conditions for hydrogen transfer to be competitive. For this reason, *tert*-butyl or thiyl leaving groups are recommended for sulfur. With faster reactions at selenium, benzylselenenides are excellent substrates for constructing selenium-containing heterocycles; competing hydrogen transfer in these systems is typically not observed.²⁰

Having established some fundamental principles and with an understanding of the kinetics of homolytic substitution processes, examples of synthetically useful chemistry involving sulfur, selenium, and tellurium are now presented.

3.2 Ring Closures at Sulfur

Intramolecular homolytic substitution at sulfur has received considerable attention, and there are several reports in the literature that provide reliable methods for the synthesis of sulfur-containing heterocycles. Examples can be found of alkyl, aryl, and acyl radicals undergoing this chemistry efficiently at the sulfur atom in sulfides,⁵ sulfoxides,^{12,22,23} sulfinates,^{24–26} and sulfonamides,^{24–26} but not at sulfones.^{22,27}

Scheme 7 illustrates the application of this chemistry to the preparation of the dihydrobenzothiophene-containing tocopherol-like antioxidant (**2**); α -tocopherol is the main component of vitamin E. In the key step, aryl radical (**3**), generated under standard conditions, was able to undergo homolytic substitution at sulfur; subsequent deprotection gave 5-hydroxy-

2,3-dihydrobenzo[*b*]thiophene (**2**) in 62% yield over two steps.²⁸ It is interesting to note that in this example, because the attacking radical is aryl, even the normally unfavorable phenyl radical can be encouraged to act as a leaving group.

Ryu and coworkers reported examples of the preparation of γ -thiolactones (e.g., **4a**) through the application of homolytic substitution by acyl radicals (**5**) at sulfur.¹⁶ The acyl radicals were generated from the corresponding acyl phenylselenide, or through the application of radical carbonylation chemistry developed in their laboratories. In the latter examples, abstraction of the bromine or iodine gives the alkyl radical (**6**) which, under a high-pressure atmosphere of carbon monoxide, forms the corresponding acyl radical (**5**) that then undergoes substitution at sulfur to give the γ -thiolactones (**4**) with expulsion of the *tert*-butyl radical (Scheme 8).

Systems examined include primary and secondary alkyl radicals generated from either bromides or iodides with good leaving groups at sulfur. The best results were obtained for the starting materials shown below. γ -Thiolactones were prepared in 86 and 75% yields from **7** and **8** respectively, while secondary iodides **9** and **10** gave the corresponding γ -thiolactones in moderate yields (Figure 1).¹⁶

A typical example of the application of this chemistry is in the preparation of **4d** from 1-(*tert*-butylthio)-2-(iodomethyl)hexane (**7**). In this case, **7** (316 mg, 1.00 mmol), *n*-tributyltin hydride (351 mg, 1.20 mmol), and AIBN (33 mg, 0.2 mmol) were dissolved in benzene (100 ml) in a 200-ml stainless steel autoclave equipped with an inserted glass liner. The vessel was pressurized to 80 atm and heated to 100 °C for 2 h. The autoclave

Scheme 8 Examples of ring closures by acyl radicals at sulfur.

Figure 1 Substrates for the preparation of γ -thiolactones by radical carbonylation/homolytic substitution methodology.

was cooled to room temperature and the pressure released before the solvent was removed *in vacuo*. β -Butyl- γ -thiobutylactone (**4d**) was obtained (135 mg, 86%) after column chromatography.

This methodology was further extended to include α,β -unsaturated acyl radicals, as well as acyl radicals generated from aryl radicals, to yield the corresponding thiolactones (e.g., **11**, **12**) in good yields (Scheme 9).¹⁶

There are few examples of radical substitution reactions involving oxidized sulfur. An early report

Scheme 10 Chiral sulfoxides undergo homolytic substitution with inversion of configuration.

by Beckwith and Boate showed that these reactions proceed with inversion of configuration, consistent with the backside mechanism discussed above (Scheme 10).¹²

More recently, Malacria and coworkers reported the use of this chemistry at sulfinates and sulfonamides to afford interesting sultines and cyclic sulfonamides (**13**).^{24,25} As shown in Scheme 11, a number of variables were explored during their investigation; these included the nature of the (precursor) halide (X), the nature of the aryl ring (Y), the substitution (Z) on the tether, as well as the nature of the leaving radical (LG).

The best results were observed for the starting materials shown below. The nature of the halide did not appear to influence the efficiency of the reaction; however, the leaving radical (LG) proved to be important with *tert*-butyl giving the highest yields

Scheme 9 Vinyl and aryl radicals are efficient in radical carbonylation/homolytic substitution chemistry.

Scheme 11 Sulfonates and sulfonamides undergo efficient homolytic substitution by aryl radicals.

Figure 2 Key substrates for radical ring closures in sulfonates and sulfonamides.

of product. Primary, benzyl, and trifluoromethyl leaving radicals proved to be less efficient. The nature of the aryl group was also investigated and this study concluded that electron-donating groups (Y) on the aryl ring were beneficial; however, electron-withdrawing groups were also tolerated, as were thiophenes. For example, sulfonates **14** and **15** led to the synthesis of the corresponding sultines (**13**, $Z = \text{O}$) in 97% and quantitative yields respectively, while cyclic sulfonamides (**13**, $Z = \text{NH}$) were prepared in 85 and 86% yields from **16** and **17**, respectively (Figure 2).

It should be noted that with aryl leaving groups (LG), intermolecular addition to LG is reported as being a competitive process, an example of which is depicted in Scheme 12.^{24,25}

Malacria also reported the use of alkyl radicals in substitution chemistry at sulfonates.^{24,25} Primary, secondary, and tertiary radicals, generated from the corresponding bromide, were all successfully employed. It should be noted that when a secondary alkyl radical is used, a new stereogenic center is created, with the size of the new substituent

Scheme 12 Homolytic addition often competes with homolytic substitution when aryl leaving groups are used in sulfonates.

influencing selectivity; the trans diastereoisomer is favored in all such examples. These alkyl sultine scaffolds are small molecule natural products that exhibit interesting olfactory and flavor properties. For example, sultine (**18**) is found in passion fruit extracts and was prepared in a 9 : 1 trans : cis mixture of diastereomers by reaction of the secondary bromide (**19**) with tris(trimethylsilyl)silane (Scheme 13),²⁵ while sultine (**20**) was formed from a tertiary radical under standard radical conditions; this compound is a component of cat's urine.²⁹

3.3 Ring Closures at Selenium and Tellurium

Radical cyclization chemistry involving selenium is generally easier to conduct than its sulfur counterpart because of the more-favorable rate constants for homolytic attack at selenium over sulfur (Table 1); consequently, since its "discovery" in the early 1990s,^{20,30,31} there have been numerous examples of this chemistry, mainly from our laboratories.^{3,17,32–35} In the case of selenium, the benzyl radical has generally been the leaving group of choice, and its use in selenium chemistry is not complicated by competing 1,*n*-hydrogen transfer chemistry because the substitution process is some 2 to 3 orders of magnitude faster than that for the similar reaction involving sulfur.²⁰ However, because of the increased reactivity of the selenium atom toward radicals, that include chain-carrying radicals such as *n*-tributylstannyl,² most of the

Scheme 13 Alkyl radicals give rise to interesting sultines, sometimes with excellent stereocontrol.

Scheme 14 Formation of dihydrobenzo[*b*]tellurophenes by intramolecular homolytic substitution chemistry.

synthetically useful homolytic chemistry carried out at selenium has utilized the (more reactive) iodide (over the bromide) as radical precursor, or has made use of precursors that do not require chain-carriers.^{30,31,33–39}

In contrast, there are relatively few examples of intramolecular homolytic substitution reactions at tellurium, and this can be attributed to a number of factors that include (i) the intrinsic photolability of organic tellurides, (ii) the propensity for organic tellurides to react with oxygen, and (iii) their

intrinsic reactivity toward chain-carrying radicals; indeed organic tellurides are often more reactive toward radicals such as *n*-tributylstannyl, than are the corresponding iodides.^{2,21} Nevertheless, there are some examples of this chemistry (see below), and success required the invention of new ways of generating radicals in the presence of tellurium, in particular, the use of aryl iodides together with sodium *n*-butyltelluroate.^{21,40}

In the example provided in Scheme 14, 2, 3-dihydro-3-hydroxy-3-methylbenzo[*b*]tellurophene

21 was isolated in 62% yield upon treatment of the aryl iodide (**22**) with sodium *n*-butyltellurolate generated *in situ*.^{21,40} Under these reaction conditions (in the dark) **22** undergoes single-electron transfer to generate the aryl radical **23**, which undergoes homolytic substitution at tellurium to give the required product.⁴⁰ It should be noted from the data in Table 1 that the nature of the leaving group at tellurium is essentially irrelevant in this chemistry because even the *n*-butyltelluride (last entry) ring closes with a rate constant in excess of 10^9 s^{-1} at 80°C .²¹

The experimental procedure for the preparation of **21** is as follows: sodium borohydride (47 mg, 1.24 mmol) was added to a solution of di-*n*-butyl ditelluride (216 mg, 0.59 mmol) in tetrahydrofuran (2 ml). The reaction vessel was purged with nitrogen, and methanol (circa 1 ml) was added dropwise, with caution, until a persistent pale yellow solution was obtained. 1-(2-iodophenyl)-1-methyloxirane (**22**) (118 mg, 0.45 mmol) in tetrahydrofuran (1 ml) was added rapidly and the resultant mixture was stirred overnight, shielded from background light. Following aqueous work up, the residue was purified

by column chromatography to give 2,3-dihydro-3-hydroxy-3-methyl-benzo[*b*]tellurophene(**21**) as a yellow solid (74 mg, 62%) with a melting point of $71\text{--}73^\circ\text{C}$.

This methodology was also successfully applied to the preparation of tocopherol-like antioxidants containing selenium (**24**) and tellurium (**25**) in yields of 65 and 47%, respectively (Scheme 15).⁴⁰

Intramolecular homolytic substitution at selenium was the key step in the synthesis of selenotocopherol reported by Engman *et al.*⁴¹ As shown in Scheme 16, the alcohol (**26**) was reacted with oxalyl chloride followed by 2-mercaptopyridine N-oxide. The pyridine-2-thioneoxycarbonyl (PTOC) imidate ester precursor (**27**) was formed *in situ* and upon heating gave the selenochroman (**28**) presumably by through a process involving the tertiary radical **29**. Subsequent deprotection of **28** with borontrifluoride gave the racemic selenotocopherol.

The use of thiohydroximate esters (PTOC, Barton, Kim esters) as carbon-centered radical precursors has the advantage that chain-carrying radicals such as *n*-tributylstannyl ("standard radical conditions", **Basic Concepts on Radical Chain Reactions**) can be avoided.^{31,38,39} In a further

Scheme 15 Formation of selenium and tellurium heterocycles mediated by sodium *n*-butyltellurolate.

Scheme 16 Formation of selenotocopherol through the use of intramolecular homolytic substitution chemistry involving selenium.

Scheme 17 Formation of 2,3-dihydroselenolo[2,3-b]pyridines by intramolecular homolytic substitution chemistry.

example, Fenner demonstrated that photolysis of the thiohydroximate (Kim) ester (**30**) afforded the pyridine-fused selenophene (**31**) in 89% yield.^{39,42} Presumably, this transformation involves cleavage of the nitrogen–oxygen bond to give the acyloxyl radical **32**; rapid decarboxylation generates the tertiary radical **33**, which undergoes further homolytic substitution at selenium (Scheme 17).

The synthesis of selenapenam and selenacephalosporin “core” structures as compounds of biological interest was achieved by Carland and Martin through the use of intramolecular homolytic substitution of aryl, vinyl, and

Scheme 18 Selenacephems can be prepared by radical ring-closure chemistry involving selenium.

alkyl radicals at selenium in suitably substituted 4-benzylseleno- β -lactams.^{38,43} For example, under standard radical conditions, the benzo-fused selenium-containing heterocycle **34** was prepared in 85% yield (Scheme 18). Under similar conditions both selenium-containing heterocycle **35** and selenapenam **36** were synthesized in 84 and 65% yields, respectively.

Thiohydroximate esters were also successfully employed as precursors in the synthesis of optically active selenium analogs of β -lactam antibiotics. As shown in Scheme 19, the selenapenam **37** was formed in 51% yield upon irradiation. The selenium-containing heterocyclic core (**38**) of the β -lactamase inhibitor, sulbactam (**39**) was prepared under similar conditions as a mixture of diastereoisomers which epimerized to a single compound upon standing.³⁸

Scheme 19 Selenium analogs of the β -lactamase inhibitor, sulbactam, can be prepared by homolytic substitution chemistry.

Scheme 20 Samarium iodide-mediated homolytic substitution chemistry can lead to selenium analogs of pyranose carbohydrates.

Scheme 21 Intramolecular homolytic substitution chemistry is the key step in the synthesis of *selenomilfasartan*, a potent angiotensin AT₁ receptor antagonist.

In an attempt to make water-soluble antioxidants, Zheng showed that a series 5-selenapentopyranose derivatives (**40**) could be prepared in low to moderate yields by samarium(II) iodide-mediated radical chemistry as depicted in Scheme 20.^{44,45} The key step in this chemistry involves cyclization at selenium of the samarium-containing radical (**41**).

More recently, radical cyclization reactions involving selenium have been employed in the synthesis of analogs of selective AT₁ receptor antagonists (*sartans*). In particular, Grange showed that treatment of iodide (**42**) with tris(trimethylsilyl)silane gave the selenophene-3-carboxylate (**43**) (Scheme 21),³² presumably through the action of the vinyl radical (**44**). Subsequent chemistry led to the synthesis of *selenomilfasartan* (**45**) which proved to be a more potent antagonist than the parent thiophene analog, *milfasartan*.³²

To the best of our knowledge, there is only one reported example of an oxyacyl radical involved in substitution chemistry at selenium. Lucas reported that, upon irradiation, telluroformate (**46**) affords

the cyclic selenocarbonate (**47**) in 73% yield, presumably through the involvement of radical **48** (Scheme 22).³⁶

3.4 Tandem Radical Sequences Involving Homolytic Substitution at Selenium

The application of tandem (cascade) radical chemistry to the preparation of interesting molecules is now accepted as a common place by the synthetic practitioner because it allows for the rapid one-pot construction of multiple bonds; other articles of this work are devoted to this chemistry (**Radical Cascade Reactions**). Until recently, however, there were no reported examples of tandem radical chemistry that included intramolecular homolytic substitution of a selenium atom as a key component of the overall sequence.

As shown in Scheme 23, it is possible to construct tandem sequences involving intermolecular homolytic addition followed by substitution. The chemistry depicted in Scheme 23 makes

Scheme 22 Ring closure by oxyacyl radicals at selenium can lead to interesting cyclic selenocarbonates.

Scheme 23 Examples of tandem homolytic addition/substitution sequences involving selenium.

use of the photochemical lability of diethyl 2-(phenylseleno)malonate (**49**),⁴⁶ which, upon irradiation, affords the diethyl malonyl radical. Subsequent addition at terminal alkenes or alkynes, followed by substitution at selenium gave the tetrahydroselenophenes (**50**, **51**) in 88 and 60% yields, respectively.⁴⁷ Other leaving groups were examined, with substrates **52–54** providing **50** in good to moderate yields, as depicted in Figure 3.

In a further recent example of this chemistry, Staples showed that selenochromanes can be

conveniently prepared through a tandem radical sequence involving intermolecular addition by benzylic radicals to suitably substituted alkenes, followed by intramolecular homolytic substitution at selenium. For example, irradiation of the dithiocarbonate (**55**) in the presence of methyl acrylate afforded **56** in 40% yield (Scheme 24).³³ This reaction presumably proceeds through the involvement of the radical (**57**) which adds to methyl acrylate; the adduct radical then undergoes homolytic substitution at selenium to give the observed product.

As shown in Scheme 25, this chemistry can be initiated using triethylborane/oxygen at lower temperatures; however, these reactions now require significantly electron-withdrawn alkenes to be effective; for example, *N*-benzyl maleimide gave selenochromane **58** in 71% yield. This methodology was also employed in the synthesis of the nitro-substituted and pyridyl selenochromanes **59** and **60** in good to moderate yields.

A typical protocol for one of these tandem reactions is illustrated in the synthesis of selenochromane **56**. In this case, *O*-ethyl-*S*-(2-(benzylseleno)benzyl) dithiocarbonate (**55**) (209 mg, 0.55 mmol) and methyl acrylate

Figure 3 Some substrates for tandem homolytic addition/substitution chemistry.

Scheme 24 Preparation of the selenochromane ring system using tandem radical chemistry.

Scheme 25 Examples of selenochromanes prepared by radical cyclization chemistry.

(76 ml, 0.82 mmol) were dissolved in toluene (1.5 ml) in a Pyrex tube after “degassing” by bubbling a steady stream of nitrogen through the solvent. The reaction vessel was sealed and irradiated for 12 h with a 125-W medium pressure mercury lamp at a distance of 15 cm while maintaining the temperature at 80 °C. Methyl 3,4-dihydro-2*H*-1-benzoselenin-2-carboxylate (**56**) was purified by column chromatography (5% ethyl acetate/petroleum spirits) to afford a colorless oil (0.22 mmol, 40%).³³

Staples was able to extend this novel tandem addition/substitution methodology to the preparation of benzo[*b*]selenophenes, an example of which is depicted in Scheme 26.³⁴ It should be noted that this chemistry requires the involvement of an alkane bearing an electron-withdrawing group and was inspired by the contributions of Zanardi and coworkers toward the construction of benzo[*b*]thiophenes.⁴⁸ Presumably, the diazonium salt (**61**) reacts in the presence of iron to generate the aryl radical (**62**), which then

Scheme 26 Selenium-containing angiotensin AT₁ receptor antagonists can be prepared by tandem homolytic addition/substitution chemistry.

undergoes intermolecular addition onto the alkyne. The adduct(vinyl) radical (**63**) reacts at selenium to give ethyl benzo[*b*]selenophene-2-carboxylate (**64**) in 50% yield (29% isolated yield). Despite the moderate yield, this one-pot procedure represents a significant improvement over traditional multi-step methods for the preparation of benzoselenophenes.^{49,50} Key intermediate **64** was incorporated into benzo[*b*]selenophene analogs (**65**, **66**) of the antihypertensive drugs, *milfasartan* and *eprosartan*.³⁴

4 INTRAMOLECULAR HOMOLYTIC SUBSTITUTION AT OXYGEN

Homolytic substitution at unactivated oxygen is relatively rare because of a mismatch of orbital overlap between the attacking radical and the oxygen atom. However, several examples exist of this chemistry taking place at oxygen atoms that are activated by strain or by a metal, or in peroxides that contain intrinsically weak oxygen–oxygen bonds.^{2,51,52}

Nugent and RajanBabu showed that epoxides can be used as radical precursors that can undergo electron transfer when treated with stoichiometric titanocene dichloride (see **Epoxides in Titanocene-Mediated and -Catalyzed Radical Reactions**). Ring opening of the epoxide results in the formation of an oxygen–metal bond.^{53–56}

Gansäuer and Grimme *et al.* were able to further develop this methodology to tandem radical chemistry that included a step in which the radical underwent homolytic substitution at oxygen, as depicted in Scheme 27.^{57,58} In this example, half an equivalent of 2,4,6-trimethylpyridine hydrochloride is required to liberate Cp_2TiCl_2 which is then

reduced by manganese dust (0.2 equiv) to give the reactive species, Cp_2TiCl . Ultimately, the tetrahydrofuran (**67**) was isolated in 67% yield as a single diastereomer through a process presumably involving reductive epoxide ring opening (mediated by the titanocene(III) complex), 5-exo cyclization and homolytic substitution at oxygen.

The effect of substitution of the alkene was investigated and a variety of different products were successfully synthesized under conditions similar to those in Scheme 27. The tricyclic compound (**68**) was obtained as a single isomer in 73% yield. Both the 1,3-dithiane (**69**) and diethyl malonate (**70**) systems gave similar results with the products isolated in 65 and 62% yields, respectively. Styrene substrates were also explored as radical acceptors

Figure 4 Examples of tetrahydrofurans prepared by titanium-mediated radical chemistry.

Scheme 27 Titanium-mediated homolytic substitution chemistry involving oxygen can lead to the formation of tetrahydrofurans.

Scheme 28 Improved procedure for the preparation of tetrahydrofurans by radical cyclization at oxygen.

leading to the synthesis of **71** in 52% yield (Figure 4).

Further improvements to the reaction's synthetic utility were made in a more recent study (Scheme 28).⁵⁹ Increasing reaction temperature was found to be beneficial, while a computational investigation resulted in an improvement to the catalyst being made; indeed a catalyst with increased Lewis acidity was identified to favor epoxide binding and resulted in an improvement in the product yield. Using this new procedure, tetrahydrofuran **72** was isolated in 95% yield, while key compounds **73** and **74** were isolated in 90 and 83% yields, respectively. The yield of **74** is particularly noteworthy because it is sterically hindered; indeed **74** was not formed when the original conditions were employed.

The protocol for this chemistry is illustrated by the synthesis of **72** as follows: the titanocene catalyst (61.2 mg, 0.200 mmol), collidine hydrochloride (158 mg, 1.00 mmol), and manganese dust (22 mg, 0.400 mmol) were heated under vacuum until the collidine hydrochloride began to sublime slightly before use. Then dry tetrahydrofuran (20 ml) and the epoxide (568 mg, 2.00 mmol) were added and the mixture stirred at 95 °C for 4 h. After addition

of *tert*-butyl methyl ether (10 ml), the mixture was washed with 2 M hydrochloric acid (10 ml), the aqueous layer was extracted with CH₂Cl₂ (2 × 10 ml) and *tert*-butyl methyl ether (10 ml). The combined organic layers were washed with brine (10 ml) and dried (MgSO₄). The solvents were removed under reduced pressure and the crude product was purified by column chromatography to afford **72** (597 mg, 95%) as a 5:1 mixture of diastereoisomers.

5 INTRAMOLECULAR HOMOLYTIC SUBSTITUTION AT SILICON, GERMANIUM, AND TIN

5.1 Homolytic Substitution at Silicon

The first examples of cyclization reactions involving substitution at silicon were reported by Giese and coworkers⁶⁰ and Utimoto *et al.*⁶¹ almost 20 years ago; these were included in the 1996 review.² Since then, Studer *et al.* studied the effect of aryl radicals at a variety of substituted alkoxy-silanes (**75**) as shown in Scheme 29.⁶² When

Scheme 29 Intramolecular homolytic substitution at silicon can lead to cyclic alkoxy-silanes.

Scheme 30 Tandem homolytic addition/substitution for the formation of cyclic alkoxyasilanes.

R' = dimethylphenylsilane the substitution reaction proved difficult. Only 5% of the desired alkoxyasilane (**76a**) was isolated, along with 43% of unidentified material. The authors attributed this to the strong Si–Si bond in the starting material. Better results were obtained for the tris(trimethylsilyl)silane (**75b**), leading to **76b**. Addition of sub-stoichiometric *n*-tributyltin hydride (0.5 equiv) through a syringe pump gave 91% of **76b**. The trimethylstannyl-substituted silane could be reacted with 0.2 equiv of *n*-tributyltin hydride (added in two portions) to give alkoxyasilane **76c** in 80% yield. Owing to the ease with which the Si–Sn bond could be cleaved it was concluded that stannyl-substituted silanes were most suitable for radical ring-closure chemistry at silicon.⁶²

Alkyl radicals have also been cyclized at silicon using similar methods, and tandem radical addition/substitution reactions proved to be particularly effective, enabling the efficient synthesis of alkoxyasilanes (**78**) from trimethylstannyl-substituted silanes (**77**) (Scheme 30).⁶³ These reactions could be conducted in the absence of a hydride source, and this observation led to a photochemical protocol involving sub-stoichiometric hexabutylditin (0.1 equiv). This proved to be a necessary improvement, as alkyl radicals seem to react relatively slowly in their cyclization chemistry at silicon. Stereoselectivity was also investigated and good diastereoselectivity was reported. For example, reaction of ethyl iodoacetate with a racemic silyl ether resulted in the isolation of the *trans*-alkoxyasilane (**79**) in 87% yield; **80** and **81** were also isolated in good to moderate yields (Figure 5).⁶³

Studer and coworkers also conducted important kinetic experiments and these studies provided the approximate rate constants for radical ring closure at silicon that are listed in Table 2.⁶³ It should be noted that the data for the slower systems contain substantial errors attributed to low amounts

Figure 5 Key silacycles prepared by tandem homolytic addition/substitution.

of cyclized product detected under the reaction conditions; these numbers should be treated with caution, but are nevertheless helpful to practitioners wishing to design syntheses based on this chemistry.

As was observed for the chalcogens, rate constants for cyclization at silicon are strongly dependent on the leaving group. Not unexpectedly, increases in rate constant are observed as the leaving radical stability improves: $\text{SnMe}_3 > \text{GeMe}_3 > \text{SiMe}_3$. With values of k_c in excess of 10^5 s^{-1} at 80°C , it is not surprising that stannyl-substituted silanes are the best substrates for this chemistry. The other important variable available to silicon that is not available to the chalcogens, is substitution on the heteroatom itself. The data in Table 2 suggest that phenyl and trimethylsilyl substituents are preferred over methyl, presumably because of their stabilizing influence on the transition state during cyclization.

The knowledge gained during these earlier investigations were later exploited by Studer where they successfully coupled intramolecular addition together with homolytic substitution at silicon to achieve a stereocontrolled synthesis of cyclic vinyl

Table 2 Representative rate constant data at 80 °C for homolytic ring closures at silicon (in benzene).⁶³

Radical	Leaving group	Product	k_c (s ⁻¹)
	$\cdot\text{SiMe}_3$		$\sim 10^3 - 10^4$
	$\cdot\text{GeMe}_3$		$\sim 1.5 \times 10^4$
	$\cdot\text{SnMe}_3$		1.2×10^6
	$\cdot\text{SnMe}_3$		1×10^5
	$\cdot\text{SnMe}_3$		1.5×10^5
	$\cdot\text{SnMe}_3$		2×10^6

silanes (**82**) (Scheme 31).⁶⁴ In this chemistry, abstraction of bromine provides alkyl radicals **83** which undergo 5-exo-dig cyclizations onto the alkyne to give the vinyl radical **84**. These reactive radicals are then able to undergo intramolecular substitution at silicon to afford a variety of bicyclic alkoxy silanes (**82**). The trimethylstannyl radical (leaving group) can be exploited as a radical chain carrier, meaning that these reactions can be conducted with sub-stoichiometric amounts of *n*-tributyltin hydride, often added via syringe pump.

The best results were obtained with phenyl and trimethylsilyl substitution on the vinyl radical providing the corresponding alkoxy silanes (**85** and **86**) in 86 and 84% yields, respectively. In contrast to this, only moderate yields were obtained for the alcohol **87** and the trimethylsilylmethyl-substituted product **88** (Figure 6).

Analogous methodology was applied to vinyl iodides (Scheme 32). The vinyl radicals that are generated following abstraction of the iodine atom in **89** were able to undergo homolytic substitution

Scheme 31 Vinyl radicals in intramolecular homolytic ring closures at silicon.

Figure 6 Some key cyclic alkoxyvinylsilanes produced through vinyl radical cyclizations at silicon.

at silicon to give the cyclized products which proved too difficult to isolate directly; subsequent treatment of the crude reaction mixtures with excess

methylolithium gave the corresponding ring opened vinylsilanes (**90**) in good to moderate yields.

Good stereoselectivity could be obtained when a secondary (**91**, trans:cis 93:7) or tertiary (**92**, trans:cis > 98:2) group was bound directly to the alkene, these substrates also gave the best yields. In contrast to this, the primary substituent afforded quite poor selectivity with a trans:cis ratio of only 2:1 in **93** (Figure 7). It was concluded that trans cyclization was favored as this enabled the R group and trimethylstannyl substituent to avoid coming into close proximity with one another.

Together with Studer, Ryu and coworkers were able to demonstrate the first example of an acyl radical undergoing homolytic substitution at silicon to form a silicon-containing ring (Scheme 33).⁶⁵ Abstraction of the bromine atom in **94** gives rise to the alkyl radical (**95**), which under Ryu's carbonylation conditions formed the acyl radical (**96**) which is subsequently able to undergo homolytic substitution at silicon to give diphenylsilacyclopentanone (**97**) and the trimethylstannyl radical. Using *n*-tributyltin

Scheme 32 Some ring closures at silicon from vinyl iodide substrates.

Figure 7 Key products formed from radical precursors 89.

hydride as the chain carrier, the product (**97**) was isolated in 20% yield; however, these reactions were associated with a variety of side-products. Competition between cyclization at silicon and reduction of the acyl radical was observed. Use of tris(trimethylsilyl)silane (see **Silanes as Reducing Reagents in Radical Chemistry**) suppressed the competitive formation of aldehyde (**98**) and also reduced product (**99**) while increasing the yield of silacyclopentanone to 35%.

Scheme 34 Examples of 1,4-stannyl migration from silicon to carbon.

Surprisingly, the 1-silyl-3-stannylpropane (**100**) was also isolated from these reaction mixtures in yields of 16–17%. This product can be attributed to the alkyl radical **95** undergoing the alternate frontside homolytic substitution process, resulting in 1,4-stannyl migration; competitive kinetic experiments provided a rate constant ($k_{1,4}$) of $9.3 \times 10^4 \text{ s}^{-1}$ (80°C) for the 1,4-migration of the trimethyltin group from the silicon atom to the carbon in **95**⁶⁵; $k_{1,4}$ is similar to the values of k_c provided in Table 2. Under carbonylation conditions the yields of the 1,4-stannane migration product were only moderate, while in the absence of carbon

Scheme 33 Radical carbonylation followed by ring closure at silicon is accompanied by several side-products.

Scheme 35 Some examples of 1,*n*-silyl translocations.

Scheme 36 Example of a stannane-mediated pinacol-coupling reaction.

Scheme 37 The stannacycle intermediate can sometimes be isolated.

monoxide the yield of this product was observed to increase to 65%.

The authors also explored the generality of 1,4-stannyl radical migrations (Scheme 34). Aromatic bromides (**101**) were reacted with *n*-tributyltin hydride under standard radical conditions resulting in the formation of the arylstannanes (**102**) as the only isolated products in good yields; these reactions presumably proceed through the intermediacy of radicals **103** and **104**.

There are now numerous examples of 1,*n*-translocation chemistry involving silicon, with a chiral example used to explore the stereochemical requirements of this homolytic substitution process (Scheme 5).¹¹ The majority of these reactions involve 1,2-migrations and include the radical Brook rearrangement, but there are reports of 1,3-, 1,4-, and 1,5-silyl migrations as well. Some illustrative examples of this chemistry are depicted in Scheme 35.^{66–68}

5.2 Homolytic Substitution at Germanium and Tin

Intramolecular homolytic substitution reactions that afford germanium- or tin-containing heterocycles are very rare; indeed, to the best of our knowledge, there are no examples of this chemistry involving germanium; however, Fu and Hays reported stannane-mediated intramolecular pinacol-coupling reactions than involve the formation of stannacycles.⁶⁹ As shown in Scheme 36,

Figure 8 Examples of products from stannane-mediated pinacol-coupling reactions.

Scheme 38 Examples of homolytic 1,*n*-stannyl and germeryl group translocations.

when glutaraldehyde (**104**) was reacted with *n*-tributyltin hydride under standard radical conditions, the cyclopentane-1,2-diol (**105**) could be isolated in 46% yield as a 98:1 ratio of *cis*:*trans* isomers, after aqueous work up. The authors postulate the involvement of stannacycle (**106**), formed by intramolecular homolytic substitution at

tin, which was hydrolyzed to the diol upon aqueous work up.

In support of this hypothesis, the analogous 1,3-dioxo-2-stannolane **107** could be isolated in 60% yield from the corresponding reaction of adipaldehyde with *n*-tributyltin hydride, but required omission of the final hydrolysis step in

Scheme 39 1,5-Hydrogen transfer sometimes competes with germeryl group translocation.

Scheme 40 Example of a 1,5-stannyl group translocation from oxygen to nitrogen.

the overall sequence.⁶⁹ Presumably, addition of the *n*-tributylstannyl radical to one of the aldehydes generates the radical **108** that cyclizes in a 6-exo manner onto the remaining aldehyde to afford the alkoxy radical **109**. The mechanistic sequence is completed when cyclization of **109** at tin provides the 1,3-dioxa-2-stannolane **107** and a chain-carrying *n*-tributyltin radical (Scheme 37).

A variety of pinacol-coupling products were successfully prepared using this methodology, with 1,5-dicarbonyl substrates exhibiting high diastereoselectivity for the corresponding *cis* diol. For example, the diol **110** was obtained in good yield (88%) but with poor stereoselectivity (1 : 1.6 ratio *cis* : *trans*) while **111** was obtained as a 99 : 1 mixture

Figure 9 Some products from intramolecular homolytic transfers from oxygen to nitrogen.

of *cis* : *trans* isomers, but in lower yield. Cyclization of ketones was also possible, but in moderate yields; for example, **112** and **113** were isolated in 62 and 53% yields, respectively and in identical (20 : 1) *cis* : *trans* ratio (Figure 8).

There are several reported examples of 1,*n*-germyl and stannyl radical translocation reactions, and the majority of these are discussed in the 1996 review.² However, some examples are included in this article for completeness (Scheme 38). Treatment of epoxide (**114**) with *n*-tributyltin deuteride under standard radical conditions afforded the spiro-fused bicycles (**115**, **116**) in moderate yield in a process that involves a 1,5-translocation of the *n*-tributylstannyl radical between oxygen centers, followed by either 6-exo-trig or 7-endo-trig ring closures.⁷⁰ Similar chemistry involving the oxetane (**117**) resulted in the analogous 1,6-translocation of the tin substituent,⁷⁰ while treatment of epoxide (**118**) with triphenylgermanium hydride resulted in a 60% yield of the germyl ether (**119**).⁷¹

It is important to note that, as observed in homolytic substitution chemistry involving sulfur, if there are abstractable hydrogen atoms available, 1,*n*-hydrogen atom transfer will compete with homolytic substitution at the less reactive elements (Si, Ge) as illustrated (Scheme 39) in the conversion of epoxide (**120**) to the germanes (**121**, **122**).⁷¹

During the past decade, Kim and coworkers reported a 1,5-translocation of a stannyl radical from oxygen to nitrogen.⁷² As shown in Scheme 40, the aziridine (**123**), when reacted with *n*-tributyltin deuteride under standard radical conditions afforded

ketones **124** and **125** in 90% overall yield, after aqueous work up. Deuterium labeling allowed the product (**126**) obtained from homolytic translocation of the tin-containing group at stannane to be distinguished from the product of direct reduction (**127**).

Presumably, the *n*-tributylstannyl radical adds to the ketone with subsequent or concerted rapid ring opening of the aziridine to give the nitrogen-centered radical **126**; direct reduction of **126** gives **124**. Alternatively **126** can undergo a 1,5-translocation to give **127**, which ultimately leads to ketone **125** (Scheme 40).

A number of other aziridines displayed similar reactivity providing the products (**128–130**) of translocation in good overall yield after hydrolysis (Figure 9).⁷²

6 CONCLUSION

Intramolecular homolytic substitution chemistry offers the synthetic practitioner efficient and convenient methods for the preparation of higher heterocycles that complement existing ionic processes, especially for the preparation of ring systems containing sulfur and selenium, as well as silicon. As was observed during the free radical “renaissance period,”⁷³ important discoveries made in the field of intramolecular homolytic addition chemistry led to an appreciation of the factors that control carbon–carbon bond forming chemistry and this information revolutionized the acceptance of radical chemistry in synthesis. Similar key studies have led to an understanding of the factors that control homolytic substitution chemistry. There are now numerous examples of radical ring-closure reactions at sulfur, selenium, silicon and fewer examples involving tellurium and tin. It is particularly rewarding to see this chemistry being applied to molecules of biological significance that include potential next-generation antihypertensive drugs. We look forward to this chemistry developing further through exciting discoveries that are just around the corner.

Stereoselective Radical Reactions

Yong-Hua Yang and Mukund P. Sibi

Department of Chemistry and Biochemistry, North Dakota State University, Fargo, ND, USA

1 INTRODUCTION

Radical reactions generally proceed under mild and/or neutral conditions and avoid harsh basic or acidic conditions that can promote decomposition or epimerization of sensitive organic functional groups. It is well known that stereochemical control with radical intermediates is a challenge as radicals are generally planar or nearly planar.¹ The increased understanding of radical chemistry and developments in Lewis acid-mediated catalysis has led to great advancements in stereoselective radical reactions. Several reviews that provide details on various aspects of stereoselective radical chemistry have appeared in the past decade.^{1–9} This article provides an overview on the development of stereoselective radical chemistry and includes both diastereo- and enantioselective reactions. The emerging field on the use of organocatalysts to control stereochemistry in radical reactions is discussed in some detail.

2 DIASTEREOSELECTIVE RADICAL REACTIONS

Diastereoselectivity in radical reactions can be established through either a substrate-controlled approach or a chiral-auxiliary-assisted process. Stereoelectronic effects play an important role in determining the level of diastereoselectivity in radical reactions. In general, stereocontrol in cyclic systems are easier to establish in contrast to reactions with acyclic systems. Diastereoselectivity in radical

cyclizations and reactions of cyclic radicals are well understood and many examples of highly selective reactions have been reported in the literature. Since the 1990s, scientists have made significant inroad into understanding acyclic stereoselection in radical chemistry and now the literature has a plethora of examples in which high diastereoselectivity is observed.

2.1 Substrate-Controlled Diastereoselective Radical Reactions

2.1.1 Acyclic 1,2-Induction in Radical Reactions

Hart, Guindon, and Giese have demonstrated that stereocontrol could occur from a center adjacent to a radical carbon atom (1,2-induction) that is substituted by ester or amide groups. Giese has systematically studied reductive tertiary butyl radical addition to α,β -unsaturated ester **1**. As shown in Scheme 1, the diastereoselectivity of the reaction could reach up to 27 : 1 for product **2** and allylic strain effect was used to explain this outcome. A radical adjacent to an ester group is a planar heteroallyl radical system (see side view of radical intermediate **3**). Because of allylic strain, this radical adopts a preferred conformation in which the C–H bond at the carbon center points in the direction of the carbonyl oxygen atom. In this preferred conformation, the ester and tertiary butyl groups shield different faces of the planar radical carbon center. The result showed

Scheme 1 Acyclic 1,2-stereoreduction in radical reactions.

Table 1 Effect of radical traps on 1,2-asymmetric induction.

R ¹	R ²	5 : 6	
		Bu ₃ Sn-D	Bu ₃ SnAllyl
<i>t</i> -Bu	Me	7 : 1	16 : 1
PhMe ₂ Si	Me	9 : 1	4.5 : 1
Ph	Me	1 : 1.4	1 : 2.8
Ph	OMe	4 : 1	17 : 1

that hydrogen abstraction occurred anti to the bulky tertiary butyl group.^{10,11}

Similar trend in selectivity was also observed using different radical trapping agents in 1,2-stereoreduction experiments using intermediates **4**. The degree of stereoselectivity (**5**:**6**) depended significantly on the reagent involved in the reaction (Table 1).¹²

Reduction of α -alkoxy radicals proceeds with modest selectivity. As an example, radical intermediate **7** gave predominantly *syn*-**8** in reduction with tris(trimethylsilyl)silane (TTMSS) (Scheme 2). The selectivity was explained using a Felkin–Anh model and was further confirmed by calculations and ESR experiments.^{13,14}

Scheme 2 Diastereoselective reduction of α -alkoxy radicals.

2.1.2 1,3- and 1,*n*-Stereoreduction

In multicomponent radical reactions, acyclic stereocontrol may be achieved, in principle, by 1,3-steric interactions of the ultimate chiral center in the telomer chain with the radical terminus of the growing chain. This interaction is usually small due to the conformational mobility of the chain. Porter and coworkers observed anti selectivity in the telomer formation by simple chain 1,3-stereocontrol of tandem free radical addition-transfer reaction when using achiral 2-oxazolidinone **9** as the template.¹⁵ Dipole–dipole stabilization for the anti transition state accounts for the observed selectivity in this double radical addition reaction (erythro **10** : threo **10**, Scheme 3).

The same strategy was also successfully applied to the synthesis of enantiomerically pure *anti*-2,4-dialkylglutaric acid via an allyl transfer reaction. As shown in Scheme 4, the enantiomerically pure selenide diastereomers (*R,R*)-**11** and (*R,S*)-**11** on reaction with allyltributylstannane under standard conditions gave the allylated products **12** in a 86 : 14 diastereomer ratio.

Hanessian *et al.*¹⁶ used hydrogen bonding as a stereocontrolling element in free radical C-allylation reactions. As shown in Table 2, high stereoselectivity can be obtained in 1,2-, 1,3-, 1,4-, and 1,5-asymmetric induction in the free radical C-allylation of α -acyl radicals derived from a series of *N*-substituted acyclic amino acid derivatives **13**. It is interesting to note that the level of stereoreduction (**14**:**15**) depends on the distance between the two stereocenters: 1,2-stereoreduction is larger

Scheme 3 1,3-Acyclic control in free radical reaction.

Scheme 4 Stereoselective allylation via 1,3-induction.

Table 2 Hydrogen bonding as a stereocontrolling element in free radical *C*-allylation reaction.

Entry	<i>n</i>	R ¹	R ²	<i>anti/syn</i>	Yield (%)

4	3	I	NMe ₂	26:74	72

than 1,3 and 1,*n*-stereinduction. Intramolecular H-bonding was believed to be the reason for the high diastereoselectivities in this work. Stereochemistry of 1,2-induction was explained using model **13a**, where a hydrogen bond exists between the N–H hydrogen atom and the carbonyl group (Table 2).

2.1.3 Radical Polar Crossover Reactions

Radical polar crossover reaction is a cascade process involving conversion of an intermediate radical formed by its addition to a neutral species, an anion, or a cation (see **Organic Electron Donors**).

The so formed intermediate is further reacted with an appropriate electrophile or a nucleophile. Alternatively, addition of a nucleophile to an unsaturated system is followed by oxidation to a radical, which is then utilized in a new bond forming reaction. Stereochemistry can be established in the first, second, or both steps.^{17,18}

Example of a radical polar crossover reaction that begins with the regioselective addition of *tert*-butyl radical to the fumarate derivative **16** is shown in Scheme 5.¹⁹ The intermediate radical is converted to a zinc enolate that is subsequently trapped *in situ* by benzaldehyde. The product **17** is isolated as a mixture of diastereomers (87:13). It is important to note that stereochemistry is established in the second ionic step leading to the formation of lactone **18**.

Jahn *et al.*²⁰ reported a different type of radical polar crossover reaction, where the conjugate addition between α,β -unsaturated ester **19** and an amine nucleophile **20** results in the formation of an enolate intermediate **21**. This is followed by conversion of the anion to a radical intermediate **22** by the addition of a single electron transfer (SET) reagent ferrocenium hexafluorophosphate. The intermediate electrophilic radical undergoes a 5-exo cyclization furnishing a nucleophilic radical that is trapped by 2,2,6,6-tetramethylpiperidin-1-oxyl (TEMPO) to furnish products **23a** and **b** in good yield with a diastereomeric ratio of 5.8:1 (Scheme 6). Stereochemistry is established in both the ionic step as well as during radical cyclization.

2.1.4 Radical Cyclizations

Intramolecular radical reactions (cyclization) to form five- and six-membered rings are often used to synthesize carbocycles, heterocycles, and polycyclic products because high diastereoselectivities are usually observed for these processes. Diastereoselectivity of 5-exo and 6-exo radical cyclizations

Scheme 5 Dimethylzinc-mediated radical polar crossover reaction.

could be explained using a chair-like transition state model. Chair-like conformation allows for an efficient overlap of the singly occupied molecular orbital (SOMO) of the radical and the HOMO of the alkene. Substituents at C1-4 prefer to adopt pseudo-equatorial positions in the transition state to avoid 1,3-diaxial interactions and this governs the relative orientations of the substituents in the cyclized products.¹

Naito and coworkers have reported a tandem thiyl radical addition to an alkene **24** followed by a 5-exo cyclization onto an oxime ether (Scheme 7). This tandem reaction gave the substituted pyrrolidine **25** in good diastereoselectivity for the cyclization (4:1) and near perfect 1,2-stereoselection with respect to the resident chiral center (anti rule, vide infra).²¹ The relative stereochemistry of the product was explained using a chair-like radical intermediate **26**.¹

A chair-like model was also used to explain the 6-exo cyclization of iodoalkene **27**. As shown in Scheme 8, an atom transfer cyclization proceeds with excellent diastereoselectivity (**28**:**29** $\geq 95:5$) using catalytic amount of $\text{Me}_3\text{SnSnMe}_3$ under photolytic conditions. The product stereochemistry can be explained by placing the ester group in an axial orientation and the alkene in an equatorial orientation in a six-membered transition state (**30**).²²

An annulation reaction is defined as a *ring-forming process* in which two molecular fragments are coupled with the formation of two new bonds. The reaction involves the addition of a radical to a neutral species, leading to a product radical, which then cyclizes to form a ring. As an example, the radical derived from 2-iodomalonate **31** using triethylborane as an initiator adds to

oct-1-ene **32** regioselectively. The newly formed radical intermediate then cyclizes selectively in a 5-exo process to produce *cis*-**33** as the major product after an azide group transfer process (Scheme 9).²³

2.1.5 Reaction of Cyclic Radicals

Compared to acyclic systems, cyclic radicals have less number of conformations, which simplifies prediction of stereochemistry in their reactions. Generally, the anti rule applies to reactions with cyclic radicals. Reactions occur preferentially in an anti manner to the substituents present in the cyclic moiety to minimize steric interactions in the transition state.²⁴ For example, excellent diastereoselectivity was observed in the allylation reaction of β -lactam **34** and allyltributylstannane leading to **35**. The allylation occurred selectively from the bottom face of cyclic radical intermediate **36** so as to avoid steric interactions with the sulfone group (Scheme 10).²⁵

Reactions of radicals in five-membered ring systems usually give high diastereoselectivities. For example, only *trans* product **38** was observed in the allylation of the bromolactone **37** (Scheme 11).²⁶ In another example, tertiary butyl radical addition to unsaturated lactone **39** followed by reduction furnished the product in moderate diastereoselectivity. In this example, the diastereoselectivity was established during the hydrogen atom transfer step. The *cis* isomer **40a** was obtained as the major product when using TTMSS as the hydrogen atom source (see **Silanes as Reducing Reagents in Radical**

Scheme 6 Radical polar crossover reaction initiated by ionic conjugate addition.

Scheme 7 Diastereoselectivity of 5-exo-cyclization.

Chemistry), which is in accordance with the anti rule.²⁷

Reactions of radicals on a six-membered ring have been investigated extensively due to their importance in natural product synthesis as well as in carbohydrate chemistry. Generally, the anti rule is still valid in reactions with β -substituted cyclohexyl radicals. The level of the anti attack is usually higher when the β -substituent is axial than when it is equatorial. In the reductive radical alkylation of enamine **41**, for instance, the *cis* isomer **42** was obtained as the major product (Scheme 12).²⁸ The stereochemical outcome could be rationalized by

transition state **43**, where hydrogen atom transfer reagent approaches the intermediate from an anti orientation to the axial sulfonylmethyl group. In another example, the intramolecular atom transfer reaction of **44** furnished the bicyclic product **45** in good yield and high selectivity when using bromotrichloromethane as an atom transfer reagent. In the key atom transfer step, the cyclohexyl radical undergoes halogen atom transfer anti to the neighboring substituent (1,2-stereoselection) yielding **45** with high diastereoselectivity.²⁹

Prediction of stereochemistry for reaction of cyclic radicals becomes complicated when the substrate has more than one substituent. In these cases, one needs to take into account other factors such as conformation of the intermediate, effect of neighboring group, stereoelectronic effect, and position of the transition state in understanding the level and sense of stereoinduction.

2.2 Chiral Auxiliary-Assisted Diastereoselective Radical Reactions

Chiral auxiliary is a chemical entity that is temporarily incorporated into a substrate to enable reactions at its prochiral unit selectively. The stereocenter in the auxiliary allows for the installation

Scheme 8 Diastereoselective 6-exo-cyclization.

Scheme 9 Stereoselectivity in [3 + 2]-radical annulation.

Scheme 10 Diastereoselective allylation of radicals in four-membered ring system.

of a new stereocenter in the substrate using steric hindrance or directing groups to provide diastereomeric adducts. Removal of the chiral auxiliary from the adducts results in the formation of enantioenriched products. A variety of chiral auxiliaries derived from amino acids, carbohydrates, and terpenes have been used for diastereoselective radical reactions.³⁰

The first example of stereochemical control in free radical addition to an alkene utilized

2,5-dimethylpyrroline carboxamide as the chiral auxiliary. The nucleophilic hexyl radical adds regioselectively β - to the keto carbonyl of substrate **46** to furnish **47**. The stereochemistry in the radical conjugate addition is controlled by the C_2 symmetric pyrrolidine amide (see **48**, Scheme 13). Diastereoselectivity of up to 97 : 3 could be obtained for conjugate addition of *n*-hexyl radical to enone **46** bearing a 2,5-dimethylpyrroline carboxamide auxiliary.³¹

Oppolzer's camphorsultam is an excellent chiral auxiliary and has been used extensively in diastereoselective radical reactions. Nucleophilic radical addition to the chiral camphorsultam-derived glyoxyl oxime **49** at -78°C afforded a 96 : 4 diastereomeric mixture of alkylated products **50** in 73% yield (Scheme 14). In this study, the *anti-s-cis* planar rotamer **A** was expected to be preferred over rotamers **B–D** in order to minimize dipole–dipole interactions between these groups, and radical addition to the *re* (bottom) face is favored to avoid the steric interaction with the axial oxygen of sulfonyl group.^{32,33}

Chiral auxiliaries could also be used to control the configuration of radicals rather than radical acceptors when attached to an appropriate radical precursor. Rosenstein and Tynan³⁴ have evaluated free radical allylation of selenide **51** bearing an oxazolidine as a chiral auxiliary for controlling stereochemistry. As shown in Scheme 15, under photolysis in dichloromethane at -78°C , the allylation could proceed with excellent diastereoselectivity (**52**, dr > 100 : 1) in 80% yield.

Garner *et al.*³⁵ have investigated diastereoselective radical decarboxylation reactions using sugar derivatives as a chiral auxiliary. In this work, an

Scheme 11 Diastereoselective allylation of radicals in five-membered ring system.

Scheme 12 Diastereoselective reactions of radicals in six-membered ring system.

ether linkage was employed to connect the chiral auxiliary and the α -alkoxy radical precursor derived from the Barton *N*-hydroxypyridine-2-thione (PTOC) esters. Radical decarboxylation of **53** occurs under photolytic conditions to form the desired α -alkoxy radical that adds to methyl acrylate resulting in the formation of an intermediate electrophilic radical. 2-Thiopyridone then traps this intermediate radical. After desulfurization of the newly formed thiopyridyl ethers using Raney

Scheme 13 Conjugate radical addition to a chiral keto amide.

Ni/EtOH, the diastereomeric ratio for product **54** could be determined as 11:1. Thus, the starting material **53** functions as a chiral hydroxyalkyl radical equivalent. A similar sequence using nitroalkenes as the radical acceptor provides a nice protocol for the synthesis of aldols (Scheme 16).³⁶

Snieckus and coworkers developed *N*-(*o*-bromo and -iodobenzoyl)-2-*tert*-butyl-perhydropyrimidinones **55** as a new chiral template for enantioselective 1,5-hydrogen atom translocation. As shown in Scheme 17, by the application of the catalytic tin method and trapping by electron-deficient olefins **56**, the addition products **57** could be obtained in moderate yields with excellent selectivities. After cleavage of the template, **57** could be converted

Scheme 14 The use of camphorsultam as a chiral auxiliary for radical addition to oximes.

Scheme 15 Radical allylation of a malonyl radical attached to a chiral auxiliary.

Scheme 16 Carbohydrate-derived chiral auxiliary in radical reactions.

into the corresponding β -substituted β -amino acid derivatives **58** with 97–98% enantiopurity.³⁷

2.3 Lewis Acid-Mediated Diastereoselective Radical Reactions

It is generally difficult to achieve high selectivity in kinetically controlled diastereoselective reactions with acyclic substrates because of their flexibility and also due to reactions proceeding from several potential transition states with similar energy levels. Lewis acid complexation of the acyclic substrate could decrease rotational degrees of freedom of the reactive intermediates and thus enhance the difference in energies between competing transition states. Lewis acid can also influence a reaction by modulating the electronic and/or steric functionalities adjacent to the site of chemical transformation.³⁸ Studies on diastereoselective radical processes under the influence of Lewis acids started in late 1980s.

As one of the earliest example, Guindon and coworkers evaluated influence of Lewis acid on radical reduction of α -iodo- β -alkoxyesters **59** (Table 3).³⁹ They found that this hydrogen transfer process, in the absence of Lewis acid, gave excellent selectivity favoring the anti isomer **60** (>25:1). The stereochemistry was best rationalized by transition state A (Table 3), which takes into account allylic 1,3-strain, dipole–dipole repulsion,

Scheme 17 1,5-Hydrogen atom transfer in optically active *N*-(*o*-bromobenzoyl)-*tert*-butylpyrimidinone.

Table 3 Effect of Lewis acid on radical reduction.

Solvent	Temperature (°C)	Additive	Yield (%)	<i>anti</i> : <i>syn</i>
Toluene	−78	—	90	>25 : 1
CH ₂ Cl ₂	−50	MgBr ₂ · OEt ₂ (25 mol%)	91	>1 : 25

A **B**

and hyperconjugative stabilization. However, when 25 mol% of MgBr₂OEt₂ was employed in this reaction, the *syn* product was formed in good yield with the diastereoselectivity of more than 1 : 25. The reversal of selectivity was explained by the formation of a chelate between the bidentate substrate and the Lewis acid (transition state **B**). Similar Lewis acid effects were also observed in allylation and atom transfer reactions.⁴⁰

Samarium iodide is a versatile reagent that is used extensively in radical chemistry (see **Organic Synthesis Using Samarium Diiodide**). As an excellent SET reagent, samarium iodide can reduce a variety of aldehydes and ketones to form ketyl radical anions, which then can undergo reaction with different radical acceptors. Importantly, the newly formed samarium(III) species shows

Lewis acidity and could potentially coordinate with the substrate or reaction partners. This coordination can potentially reduce the flexibility of the molecules to a certain extent. Therefore, samarium iodide-mediated radical reactions usually give good selectivities. Matsuda and coworkers showed that the samarium iodide-mediated coupling of erythro- β -hydroxyketone **61** with acrylonitrile led exclusively to the anti diol **62** in high yield.⁴¹ A six-membered chelation model **63** of Sm(III) to the β -hydroxy and the carbonyl groups was proposed to explain the stereochemical outcome for this transformation (Scheme 18).

High diastereoselectivity was also observed in SmI₂-mediated intramolecular cyclization. As shown in Scheme 19, Molander and Kenny⁴²

Scheme 18 Diastereoselectivity in samarium iodide-mediated radical reaction.

Scheme 19 Diastereoselectivity in radical cyclization mediated by SmI_2 .

reported the cyclization of olefin branched acetoacetate derivative **64** using samarium iodide. Excellent diastereoselectivity for **65** (200:1) was obtained with the formation of three contiguous stereocenters in high yield. Sm(III) species again played an important role through chelation with the ester group in a chair-like transition state **66**, which accounted for the observed selectivity.

Single-point bonding between Lewis acid and substrate could also significantly change the selectivity of radical reactions. Sato and coworkers have investigated the effect of Lewis acid in the reductive radical alkylation of α -methylenebutyrolactone **67** using *n*-BuI as the radical precursor. They found that in the absence of Lewis acid, the reaction gave high diastereoselectivity (9:1) with *syn* isomer **68** as the major product. The level of 1,3-stereoiduction is quite high because of the rigidity of the ring system. On the other hand, reaction with 1.1 equiv of ClAl(OTMP)_2 as the additive,

Table 4 Single-point binding Lewis acid-mediated radical reaction.

Additive	Yield (%)	cis : trans
—	44	9 : 1
$(\text{TMPO})_2\text{AlCl}$ (1.1 equiv)	90	1 : 1.5

the selectivity was reversed and the *trans* isomer is isolated as the major product (1:1.5). Coordination of the bulky Lewis acid to the carbonyl oxygen occurs opposite to the resident phenyl group. The phenyl group and the Lewis acid impede H-atom transfer from opposite faces and the anti product is formed with a slight preference (model **69**, Table 4).²⁷

Lewis acid-mediated diastereoselective radical reactions using chiral oxazolidinone auxiliaries have proven to be the most successful in a variety of

Table 5 Diastereoselective conjugate radical addition using chiral oxazolidinone.

C–C bond formations. Sibi *et al.*⁴³ have investigated diastereoselective conjugate radical addition to a cinnamate substrate bearing a diphenylmethyl oxazolidinone auxiliary (Table 5). In the absence of any additive, the conjugate addition proceeded in good yield. However, the selectivity was very low (1.3 : 1). In contrast, reaction using 1 equiv of Yb(OTf)₃ as the Lewis acid additive gave the product in very high selectivity of 45 : 1. Moreover, the reactivity toward radical conjugate addition also improved significantly and the yield jumped up to 90% using Yb(OTf)₃. The stereochemical outcome was rationalized using **73** as a model in which the substrate conformation was fixed by coordination between the two carbonyl groups and the Lewis acid. The radical attacks the alkene from a face

opposite to the diphenylmethyl substituent of the chiral auxiliary. The bulk of the diphenylmethyl group in the auxiliary is critically important for obtaining high selectivity. The use of a chiral auxiliary with a smaller benzyl group at C-4 led to a substantial reduction in selectivity. A similar strategy has also been successfully applied to stereoselective α -allylation and atom transfer reactions.⁴⁴

Sibi and Rheault⁴⁵ have also investigated the effect of Lewis acids in radical allylation. As shown in Table 6, Lewis acid has a significant impact on the allylation of α -bromo propionate bearing a chiral oxazolidinone auxiliary. In the absence of any Lewis acid, the reaction gave very low diastereoselectivity (1 : 1.8). Single-point bonding Lewis acid such as BF₃·OEt₂ had no impact on selectivity. In contrast, the use of MgBr₂, a chelating Lewis acid, provided very high selectivity of up to 39 : 1 for the allylation product. The stereochemistry of the product using MgBr₂ as a Lewis acid was opposite to that obtained in the absence of any Lewis acid.

Significant impact of Lewis acid on selectivity was also observed in the cyclization of vinyl iodide **76** bearing a (–)-8-phenylmenthyl chiral auxiliary. Compared to modest selectivity of 2 : 1 in the absence of Lewis acid, reaction mediated by methyl aluminum bis(2,6-di-*t*-butyl-4-methylphenoxide), a bulky Lewis acid, showed a significant improvement in stereoselectivity of up to 24 : 1 (Table 7).⁴⁶

3 ENANTIOSELECTIVE RADICAL REACTIONS

Enantioselective radical reactions have been at the forefront of new synthetic methodology development since the 1980s.^{47–49} Several strategies have been applied to control the enantioselectivity of radical reactions, which includes chirality transfer from enantioenriched reagents, assistance of metal complex, and organocatalysis. The following sections provide illustrative examples for each of the major category of enantioselective radical reactions.

3.1 Chiral Chain-Transfer Reagent

The use of chiral chain-transfer agent is a straightforward strategy for chirality induction in radical chemistry. Organotin hydride has been used as a major chain-transfer reagent and reducing agent for a long time (see **Tin Hydrides and Functional**

Group Transformations). Early investigation on the use of chiral chain-transfer reagent in enantioselective radical chemistry was focused on utilizing a chiral organotin reagent. The results showed that organotin hydride reagent based on chiral tin center provided inefficient chirality transfer and racemization were generally observed.^{50–52} Nanni and Curran⁵³ reported the first example of asymmetric induction using chiral organotin as the chain-transfer reagent based on a chiral carbon backbone. As shown in Scheme 20, chiral C₂-symmetric binaphthyl skeleton-based tin hydride **78** could reduce α -bromoketone **79** in 41% ee with Et₃B/air as the radical initiator.

Metzger and coworkers developed a chiral tin hydride **82-H**, which is similar to Curran's chiral binaphthyl organotin hydride **78** where the methyl group on the tin atom has been replaced with a bulky *t*-butyl group.⁵⁴ Using Et₃B/air as the radical initiator, chiral tin hydride **82-H** could reduce α -bromoester **81** with slightly increased enantioselectivities of up to 52% at -78°C (Table 8).

**Scheme 20** Reduction of α -bromoketone using chiral tinhydride.

Table 8 Asymmetric reduction of α -bromoesters using chiral tinhydride.

82-X	Temperature (°C)	ee (%)
82-H (0.5 equiv)	-78	52
82-H (0.5 equiv)	24	28
82-Br (0.1 equiv) + Na(CN)BH ₃ (3 equiv)	24	26

Interestingly, the authors used substoichiometric amounts of chiral tin hydride in entries 1 and 2. The tin hydride reagent could also be generated *in situ* by the addition of sodium cyanoborohydride to chiral tin bromide **82-Br**. The enantioselectivity for the reduction product using catalytic amount of the organotin reagent was comparable to that obtained when the same reaction was conducted using stoichiometric amounts of the chiral reducing agent.

Haque and Roberts observed moderate enantioselectivities in the radical chain hydrosilylation of prochiral alkenes using catalytic amounts of an optically active thiol. As shown in Scheme 21, in the presence of 5 mol% of chiral thioglucose derivative **85**, hydrosilylation of alkene **84** gave the corresponding product **86** in good yield with 50% ee. In the key step of chirality transfer, hydrogen atom

transfer occurs from chiral thiol to radical intermediate **87** with some enantioselectivity. The thiyl radical is reduced by Ph₃SiH to regenerate the chiral catalyst. Thus, chiral thiol works as the chiral hydrogen atom source in this process.^{55–57} Additional examples of reagent-based enantioselective hydrogen atom abstraction have also been reported, which involves chiral amine-boryl and silanethiyl radicals.^{58–60}

3.2 Memory of Chirality

Memory of chirality is a phenomenon in which the chirality of the starting material is preserved in a reactive intermediate for a limited time. The concept of “memory of chirality” was proposed during alkylation of certain enolates 10 years ago.⁶¹ Typically, alkyl radicals have very low barriers to inversion and application of the principles of memory of chirality to them is quite interesting.

3.2.1 Memory of Chirality in Hydrogen Atom Transfer

Rychnovsky and coworkers observed high level of chirality preservation in the hydrogen atom transfer reaction of tetrahydropyran **88**.⁶² As shown in Scheme 22, the photo-decarboxylation of optically active Barton ester **88** leads to radical intermediate **89**, which can be trapped by PhSH as the hydrogen atom source to furnish product **92** in 86% ee.

**Scheme 21** Radical reduction using a chiral thiol as H-atom source.

Scheme 22 Memory of chirality in H-atom transfer.

Scheme 23 Memory of chirality in reductive decyanation.

Table 9 Memory of chirality in radical cyclization.

Precursor	R ¹	R ^E	R ^Z	X	Yield (%)	ee (%)
M-94a	Me	Me	H	I	73	89 (<i>R</i>)
M-94b	Me	Me	H	Br	60	92 (<i>R</i>)
M-94c	Me	Ph	Me	I	75	94 (<i>R</i>)
M-94d	Me	Me	Me	I	91	49 (<i>R</i>)
M-94e	Et	Me	I	I	93	90 (<i>R</i>)

Obviously, the hydrogen transfer process is faster than the ring inversion. It was pointed out that a slow conformational interconversion (5–10 kcal mol⁻¹) imposed a barrier to equilibration despite a very low barrier (< 0.5 kcal mol⁻¹) to radical inversion.

A memory effect was also observed in the reductive decyanation of optically active nitrile **93** (Scheme 23). Reductive decyanations of nitriles are stepwise reactions that proceed via a radical intermediate. Addition of **93** to a 6.4 M Li/NH₃ solution at –78 °C gave tetrahydropyran **92** in nearly complete memory of chirality.

3.2.2 Memory of Chirality in Cyclization

Curran *et al.*⁶³ reported a unique memory of axial chirality and its conversion to central chirality. As shown in Table 9, initiated by Et₃B/O₂, radical cyclization of *o*-haloarylanilides **94** to oxindoles **95** shows high-level chirality preservation (50–94% ee) with Bu₃SnH as the radical chain reagent. The reaction worked well for both aryl iodides and aryl bromides and the enantiomeric excesses are similar. However, cyclization of a dimethylacrylate substrate with a *Z*-alkene substituent as in **94d** gave reduced enantiomeric excess of about 50%. Higher enantiomeric excesses were obtained for **94c** with a R^E phenyl group most likely due to delocalization provided by conjugation with the phenyl ring. This stabilization of the radical intermediate increases the rate of the reaction.⁷

Although the energy barrier between **M-96** and **P-97** is not exactly known (M and P are helical chirality descriptors), high selectivity in the cyclization suggests that inversion between them is slower than radical cyclization (Scheme 24).

3.3 Chiral Lewis Acid-Mediated Enantioselective Radical Reactions

Chiral Lewis acids have been widely applied in a variety of transformations to access enantioenriched materials. Chiral Lewis acids can bind the substrate or other reacting components. Chiral Lewis acids have also been successfully utilized in radical reactions by either interaction with the substrate or the radical species.

3.3.1 Hydrogen Atom Transfer

Stereocontrol during chiral Lewis acid-mediated radical reduction at a carbon atom α to a carbonyl group can be visualized to occur in two potential

Scheme 24 Mechanism of memory of chirality in radical cyclization (cf. Table 9).

Scheme 25 Chiral Lewis acid controlled H-atom transfer.

pathways (Scheme 25). For both carbon-centered or an enol form of the radical generated in the presence of a chiral Lewis acid, the hydrogen atom donor can approach selectively to one face of either radical intermediate **99** or **100** leading to enantioenriched products.⁶⁴

Blumenstein *et al.*⁵⁴ reported an enantioselective hydrogen atom transfer reaction of α -alkyl- α -iododihydrocoumarin **101** using stoichiometric amounts of MgI_2 and a chiral diamine ligand **102** with Bu_3SnH as the hydrogen atom source (Table 10). In this study, the authors observed significant concentration effect for this reaction. At a higher concentration (around 36 mM), moderate enantioselectivities for **103** could be obtained (30–62% ee) with good chemical yields. Substrates **101a–c** gave higher selectivities than **101d**, which suggests that bidentate binding of the substrates is essential for higher enantiomeric excesses in this system.

Alkyl radicals are frequently utilized in organic synthesis and are nucleophilic in character. Their addition to an olefin substrate is enhanced by electron-withdrawing substituents on the olefinic linkage. Sato and coworkers utilized conjugate addition to generate a C-centered radical intermediate for evaluating asymmetric hydrogen atom transfer.⁶⁵ As shown in Scheme 26, a strong chiral aluminum Lewis acid **106** could promote the conjugate addition of butyl radical to α -methylenebutyrolactone **104**. Modest enantioselectivity (28%) for **105** was observed in the ensuing hydrogen atom transfer process. This study represents the first example of asymmetric radical reaction controlled by a chiral Lewis acid, though the level of asymmetric

Scheme 26

induction was still low. The activation of the substrate occurs by monodentate coordination of the Lewis acid (see A).

Sibi *et al.*⁶⁶ reported a Lewis acid-promoted hydrogen atom transfer reaction using a bidentate dehydroalanine substrate **107**, which proceeds with high enantioselectivity. As shown in Table 11, in the presence of chiral Lewis acid derived from Mg(ClO₄)₂ and Ligand **109**, the radical intermediate obtained by the addition of a variety of nucleophilic radicals to **107** underwent H-atom transfer with good selectivity to furnish **108**. Reactions with primary alkyl radicals (α -alkoxyalkyl, ethyl, and *i*-butyl) and secondary radicals (*i*-propyl and *c*-hexyl) gave good enantioselectivities (55–85%). However, reaction with the bulky tertiary butyl radical was not selective and only gave 27% ee.

This decrease in selectivity was attributed to the *tert*-butyl group and the chiral Lewis acid shielding opposite faces resulting in reaction occurring from a mono-coordinated or noncomplexed substrate. The limitation for this hydrogen atom process is that 1.3 equiv of the chiral Lewis acid is necessary to ensure good yield and enantioselectivity.

Sibi and Sausker⁶⁷ have also evaluated another bidentate substrate **110** derived from commercially available 1,8-naphthosultam template for asymmetric hydrogen atom transfer using chiral Lewis acid. As shown in Table 12, in the presence of a combination of MgBr₂ ethyl etherate and the bisoxazoline ligand **109**, the hydrogen atom transfer process proceeded to yield **111** in high enantioselectivity (80–90% ee). The nucleophilic radical could be a primary, secondary, and a tertiary alkyl radical. Importantly, the reaction proceeded smoothly using substoichiometric amounts of the chiral Lewis acid. From entries 1 and 2 in Table 12, we can discern that 30 mol% of MgBr₂ gave similar enantioselectivity compared with stoichiometric amount of the chiral Lewis acid.

3.3.2 Halogen Atom Transfer

Halogen atom transfer reactions involve homolysis of a C–X or X–X bond in a neutral molecule, followed by the transfer of both components to an unsaturated functional group. There is atom economy in such processes and these reactions provide functionality for further transformations.⁶⁸ Mero and Porter⁶⁹ reported the first chiral Lewis acid

catalyzed halogen atom transfer reaction of α -halo oxazolidinone imide **112** and 1-octene **113** using a combination of zinc triflate and phenyl bisoxazoline ligand **114** (Scheme 27). This intermolecular atom transfer process gave product **115a**. The crude product was reduced to **115b** and selectivity determined. Compound **115b** was formed in low yield (5–15%, over two steps) and modest enantioselectivity (40% ee).

In 2001, Yang *et al.*⁷⁰ described an intramolecular halogen atom transfer reaction catalyzed by a chiral Lewis acid. As shown in Table 13, using a combination of Zn(OTf)₂ and tertiary butyl bisoxazoline **117**, unsaturated β -keto esters **116a–d** underwent enantioselective bromide transfer reaction efficiently. The exocyclic products **118a–d** could be

obtained in as high as 95% ee. Interestingly, addition of 4-Å molecular sieves was very important for this reaction. Addition of molecular sieves not only led to a dramatic increase in yield and enantiomeric excess but also allowed for the use of substoichiometric amounts of the chiral Lewis acid.

Yang *et al.*⁷¹ designed diene substrates **119** and **121** for evaluating tandem bromine transfer (Scheme 28). Reaction of **119** using a stoichiometric amount of the chiral Lewis acid gave the corresponding 6-*endo* tandem cyclized product **120** in 84% ee. Although the yield was as low as 16%, this one-step reaction produces useful bicyclic ring skeleton with multiple stereocenters in an enantioselective manner. Each substrate required optimization of reaction conditions. For diene **121**, a combination

of $\text{Yb}(\text{OTf})_3$ and **PyBOX 124** proved to be optimal chiral Lewis acid and the cyclized product **122** could be obtained in 60% yield and 66% ee. Reductive debromination product **123** was always observed as the side product.

3.3.3 Reductive Alkylations

Reductive radical alkylation is a process that involves the addition of radicals to carbon–carbon or carbon–heteroatom multiple bonds followed by trapping with a hydrogen atom source. Generally, chiral Lewis acids are used to control the radical addition step in an asymmetric manner. Naito and coworkers investigated enantioselective radical additions to $\text{C}=\text{N}$ of oxime ether **125** derived from glyoxylate using chiral Lewis acids (Scheme 29).⁷² Several combinations of chiral ligands and Lewis acids were evaluated. Stoichiometric amount of MgBr_2 and phenyl bisoxazoline ligand **114** gave the best result and furnished product **126** with excellent yield and moderate enantioselectivity (52% ee). A tetrahedral model, **127**, was proposed to explain the stereochemical outcome of the reaction.

Friestad *et al.*⁷³ have also reported chiral Lewis acid-mediated reductive radical alkylation of carbon nitrogen double bond. In their study, a combination of copper triflate and bisoxazoline ligand **117** could promote the radical reductive alkylation of valerolactam-derived *N*-acyl hydrazone **128** with high enantioselectivity. As shown in Table 14, in the presence of stoichiometric amount of chiral Lewis

acid, the enantiomeric excess for the isopropyl radical adduct **129** could reach as high as 95%. However, the enantioselectivity decreases dramatically when the reactions are carried out with substoichiometric amount of the chiral Lewis acid. The lower catalyst loading did not impact the yield of the reaction.

Asymmetric conjugate radical addition to electron-deficient carbon–carbon double bond followed by hydrogen atom transfer is one of the most successful application of chiral Lewis acid radical chemistry. In order to reach high enantioselectivity, a bidentate substrate was generally necessary. Sibi and coworkers reported the first enantioselective radical conjugate additions using substoichiometric amount of a chiral Lewis acid (10 mol%). Conjugate addition of isopropyl radical to oxazolidinone-derived substrate **130** using MgI_2 /ligand **109** as a chiral Lewis acid gave the product **131** in 88% yield and excellent enantioselectivity (95% ee) (Table 15). It was observed that a substrate capable of bidentate chelation to the chiral Lewis acid was very important to activate it toward radical addition at low temperature. The chelation also helped the substrate adopt an *s*-cis orientation at the $\text{C}(\text{O})\text{--C}(\text{sp}^2)$ bond and provide optimal face shielding (see model **131a**).^{74,75}

Sibi and Shay⁷⁶ showed that achiral template played an important role in the outcome of enantioselective reductive radical alkylation to $\text{C}=\text{C}$ bond. By changing the oxazolidinone template of **130** to a 3,5-dimethylpyrazole in **132** resulted in a reversal of stereochemistry using the same chiral Lewis acid (Scheme 30). Radical addition in the presence of stoichiometric amounts of zinc triflate and ligand

$\text{Zn}(\text{OTf})_2$ (1.0)	—	53

109 gave good yields and moderate selectivities for **133**. Chiral Lewis acid coordinates with acylated pyrazoles **132** and forms a five-membered chelate unlike the six-membered chelate formed with oxazolidinones **130** (vide supra). This change in chelate ring size, accompanied by a *trans*-octahedral geometry with **132** and **109**, has been proposed to account for the reversal of enantioselectivity (see **134**).

α' -Phosphoric enone has also been examined in enantioselective conjugate radical additions by Lee and Kim (Scheme 31).⁷⁷ Radical addition to **135** using $\text{Et}_3\text{B}/\text{O}_2$ as a radical initiator, Bu_3SnH as the hydrogen atom source, and a chiral Lewis acid (30 mol%) derived from zinc triflate and bisoxazoline **136** gave high yields for the conjugate addition product **137**. The chemical efficiency and level of enantioselectivities (82–95% ee) were excellent using a variety of primary, secondary, and tertiary alkyl radicals. Reaction with β -alkyl and aryl substrates were evaluated and found to be effective.

Radical addition to α,β -disubstituted enoates is difficult because the substrates are less reactive for both steric and electronic reasons. Sibi and coworkers have reported the use of tertiary butyl imide as the template in conjugate radical additions to α,β -disubstituted enoals. This template provided reactivity enhancements as well as the ability to control rotamers in α -substituted acrylates. Radical

Scheme 30 Template effect in chiral Lewis acid-mediated reductive radical alkylation.

Scheme 31 Chiral Lewis acid-mediated reductive alkylation of α -phosphoric enones.

addition to the tiglate substrate **138** in the presence of 30 mol% chiral Lewis acid derived from MgI_2 and bisoxazoline ligand **117** gave the radical addition/trapping products **139** with excellent diastereo- and enantioselectivities (Table 16). A variety of alkyl radicals could be used in this reaction (entries 1–3). This reaction system has a wide substrate scope and R^2 could vary from alkyl to aryl group. The anti diastereomer was formed as the major product in all cases and the level of enantioselectivity was also high for most of the reactions.⁷⁸

Castle and coworkers⁷⁹ have examined radical conjugate addition/trapping reaction using β -substituted α,β -unsaturated α -nitro ester and amide **140** as substrates (Table 17). The reaction was promoted by a chiral Lewis acid prepared from $\text{Mg}(\text{NTf}_2)_2$ and DBFOX (**141**). Reactions were efficient when a stoichiometric amount of chiral Lewis acid was employed yielding the product **142** in good yield and high enantioselectivity. The diastereomeric ratio was nearly 1 : 1. Reaction with 50 mol%

of the catalyst was equally efficient. However, lowering the catalyst loading to 30 mol% gave the diastereomeric products in low enantioselectivity. The products could be converted to β -substituted α -amino acids (**143**) in good yield and good enantioselectivity.

In all reported enantioselective radical addition/trapping reactions that proceed with high selectivity, detachable achiral auxiliaries play a pivotal role. These auxiliaries not only provide an extra donor atom that enables Lewis acid chelation, but they also allow for control of the rotamer geometry of the substrate. Sibi and Zimmerman⁸⁰ have examined radical addition/trapping reaction of hydroxypyrones using chiral Lewis acids. Since this substrate has a fixed s-trans geometry, no achiral auxiliary was needed to control rotamer geometry. Commercially available kojic acid proved to be a good substrate to evaluate chiral salen (salen = *N,N'*-bis(salicylidene)ethylenediamine dianion) Lewis acid **146** catalyzed radical

addition/trapping reactions. Protection of the C-6 hydroxyl group increased substrate solubility and deactivated the C-6 position toward conjugate radical addition. Radical addition to either substrate

144 or **145** gave exclusively C-2 addition products **147** and **148** under standard reductive radical alkylation conditions. This condition was quite efficient for bulky tertiary radicals and excellent diastereo- and enantioselectivities were observed for all cases (entries 3–4 and 7–9, Table 18). On the other hand, secondary radicals examined in this study gave 72–76% ee for both substrates. A model **149** in which the pyrone carbonyl coordinates the Al-salen Lewis acid was proposed to explain the stereochemical outcome. The stereochemistry of hydrogen atom transfer step was believed to be controlled by the newly formed β -stereocenter with radical R group shielding the top face.

Sibi and Nad⁸¹ have evaluated the reductive radical alkylation of exo-methylene cyclohexanones **150** with fixed *s-cis* geometry (Scheme 32). As shown in Scheme 26, single-point bonding chiral salen-derived Lewis acid **146** was the best catalyst for the reaction. Excellent diastereo- and enantioselectivity could be obtained for isopropyl radical under standard conditions furnishing **151** in good yield (95% ee, dr $\geq$ 99 : 1). This reaction provides a method to synthesize enantioenriched cyclic aldols via radical reaction with the formation of two stereogenic centers in a single operation.

The use of tin reagents as a radical mediator is well known (see **Tin Hydrides and Functional Group Transformations**). Tin reagents are toxic and tin byproducts are difficult

Table 18 Chiral Lewis acid-mediated radical reductive alkylation of single-point binding substrates.

to remove during purification. Several alternatives to tin reagents have been reported in the literature and these include silanes, thiols, phosphorus acids, indium hydrides, and cyclohexadienes. Generally, higher temperature is required if one uses a nontin reagent as the radical chain carrier. However, Lewis acid-mediated asymmetric radical reactions are generally conducted at low temperatures, which necessitate the use of an efficient radical chain carrier such as tin hydride. Sibi *et al.*⁸² have explored the possibility of chiral Lewis acid-mediated nontin radical conjugate addition/trapping process. A variety of nontoxic silanes were evaluated in enantioselective radical conjugate additions (Table 19). Radical addition to **152** in the presence of 30 mol%

of Mg(NTf₂)₂ and chiral bisoxazoline **109** using less toxic and inexpensive hexyl silane gave the addition product **153** in good yield and selectivity. The reactions were conducted at room temperature. Reactions with primary and secondary alkyl radicals gave ethyl radical adduct as a side product.⁸³

3.3.4 Fragmentations

Fragmentation reactions involve the addition of radicals to a neutral molecule followed by β -elimination from the resulting radical generating an olefin. Generally, allyl group transfer between electrophilic radicals and allylstannanes or allylsilanes has been

Scheme 32 Chiral Lewis acid-mediated reductive alkylation of an enone with a fixed *s*-cis geometry.

used frequently in organic synthesis. Chiral Lewis acid-promoted asymmetric fragmentations have also attracted attention. Porter *et al.*⁸⁴ reported highly enantioselective radical transformations involving reaction of α -halo oxazolidinones with allylsilanes using a chiral Lewis acid derived from MgI_2 or $\text{Zn}(\text{OTf})_2$ and a bisoxazoline ligand. Reaction of α -bromoacyl oxazolidinone **154** with allylstannane or allylsilane mediated by a bidentate chiral Lewis acid proceeded smoothly in good chemical yield to furnish the allylated product **155** in $\sim 90\%$ ee. With respect to enantioselectivity, allylsilanes worked better than allylstannanes in this particular reaction

for both substrates **154a** and **154b** (compare entries 1 and 3 with the entries 2, 4, and 5) (Table 20).

Chiral Lewis acid-mediated fragmentation has also been used to construct all carbon chiral quaternary centers. Hoshino and coworkers evaluated different chiral Lewis acids for radical allylation of α -substituted- α -iodolactones **156** and **157** using allylstannane.⁸⁵ As shown in Table 21, a chiral aluminum Lewis acid prepared from trimethylaluminum and ligand **159** could activate the substrates to provide the desired allylated products **158** in good yields with 27 and 3% ee, respectively. It was found that addition of diethyl ether (1 equiv with

respect to Lewis acid and ligand) led to a dramatic increase in enantioselectivity to 81 and 92% for both substrates. More significantly, the catalyst loading could be lowered to 20 mol% without significant erosion in enantioselectivity. A single-point bonding model between lactone carbonyl oxygen and chiral aluminum Lewis acid was proposed to account for the selectivity, where aluminum exists as a five-coordination complex.

3.3.5 Tandem Radical Conjugate Addition–Fragmentation Reactions

α -Acyl radicals are generally used for fragmentation reactions to access allylated products because of their electrophilicity. α -Acyl radicals can be generated not only from α -halo carbonyl compounds but also from radical conjugate additions to α,β -unsaturated carbonyl compounds. Porter and coworkers reported the first chiral Lewis acid-mediated asymmetric radical conjugate addition–fragmentation reaction (Table 22).⁸⁶ Radical addition to oxazolidinone acrylate **161** in the presence of Zn(OTf)₂/ligand **114** and allylstannane leads to the formation of the allylated product **162** in good yield and selectivity. This reaction shows strong solvent effect and a mixture of dichloromethane and pentane (4:6) proved to be the best solvent. For reaction with *t*-butyl radical, enantioselectivity as high as 90% ee could be obtained.

Table 23 Chiral Lewis acid-mediated radical conjugate addition/fragmentation with α,β -unsaturated sulfones.

Entry	Substrate	Allylstannane	Yield (%)	ee (%)
1	163	AllylBu ₃ Sn	36	46

7	164	Allyl ₂ Bu ₂ Sn	86	78
8	164	Allyl ₂ Bu ₂ Sn	80	84

Toru and coworkers investigated tandem radical addition–fragmentation reactions using α,β -unsaturated sulfones **163** and **164** attached to a pyridyl and benzimidazol template, respectively, to furnish **165** (Table 23).⁸⁷ The results showed that diallyldibutylstannane was the best allylation reagent for this fragmentation reaction. Reaction with benzimidazol sulfone **164** gave better enantioselectivity (up to 84% ee). Drawbacks to this reaction was the need for stoichiometric amount of the chiral Lewis acid and a large excess of stannane (10 equiv).

Using chiral Lewis acid-mediated radical addition/trapping strategy, Sibi and Chen⁸⁸ examined

Table 24 Chiral Lewis acid-mediated radical conjugate addition/fragmentation to construct two contiguous stereocenters.

Entry	Substrate	LA 0.3 equiv	R ¹	Yield (%)	dr	ee (%)

^a Allyltriphenyltin was used.

the potential for establishing two contiguous chiral centers with control over relative and absolute stereochemistry of the product (Table 24). Radical addition to **130** or **166** mediated by a chiral Lewis acid followed by allylation gave the corresponding radical adducts **167–168** with good to excellent enantioselectivities with predominant *anti*-stereochemistry. Enantiomeric products could be obtained by a simple change in the Lewis acid from magnesium to copper, while using the same ligand **109**.

The kojic acid derivatives discussed earlier are also excellent substrates for radical addition–fragmentation reactions. Sibi and Zimmerman⁸⁰ have evaluated radical addition/allylation to substrate **169** using salen-Al **170** as the chiral Lewis acid. Two contiguous stereocenters are established in one operation with one of them a quaternary center (Table 25). Catalyst modification with counter ion exchange from Cl to NTf₂ was required for successful execution of the reaction. The enantioselectivities are modest and similar to what was observed for reductive alkylation discussed earlier.

3.4 Organocatalysis in Radical Reactions

Organocatalysis, the use of small organic molecules to catalyze organic transformations, is relatively new and a very popular field within the domain of chiral molecule synthesis. Compared to well-established branches of catalysis (enzyme catalysis, Lewis acid catalysis, and organometallic catalysis), organocatalysis has some advantages. First, organic molecules are generally insensitive to oxygen and moisture in the atmosphere and there is no need to use special techniques to carry out the reactions. Second, a wide variety of organic reagents, such as amino acids, carbohydrates, and hydroxy acids, are available as single isomers from natural sources, and therefore, they are usually cheap and readily accessible. Third, small organic molecules are typically nontoxic and environment friendly. Several different types of organocatalyses have been developed, which includes enamine catalysis, hydrogen bonding catalysis, iminium ion catalysis, and counterion catalysts.⁸⁹ Organocatalysis for asymmetric free radical reactions is still in its infancy, although the future holds a lot of promise. Only a few examples have appeared in this area.

2	<i>c</i> -Pentyl	90	99 : 1	69

3.4.1 Organocatalysis

In 2007, MacMillan's group introduced a new concept called *SOMO catalysis*, which is based on one-electron oxidation of an electron-rich enamine. For example, reaction of aldehyde **172** with the chiral imidazolidinone **173** furnishes the enamine **175** via the iminium ion **174**. The enamine undergoes an oxidation to generate a reactive radical cation **176** with three π -electrons (Scheme 33). The electrophilicity of the SOMO of this radical intermediate allows it to react readily with a variety of weakly nucleophilic "SOMOphiles" at the α -position of the parent enamine.⁹⁰

The SOMO catalysis was demonstrated by an allylation reaction using allyltrimethylsilane as the SOMO nucleophile. As shown in Scheme 34, treatment of aldehyde **177** with 20 mol% imidazolidinone catalyst **173** and 2 equiv of ceric ammonium nitrate as the oxidant, gave (*R*)-2-allyl-octanal **178** with excellent level of enantioinduction and in good yield (91% ee, 81% yield). Moreover, a variety of chemical functionalities were inert under this oxidative condition, including olefins, ketones, esters, and carbamates.

Sibi and Hasegawa⁹¹ independently reported another example of organocatalysis in radical chemistry (Scheme 35). In this study, commercially available stable radical TEMPO was used to trap the radical intermediate formed through oxidation

**Scheme 33** Radical reactions with organic catalysts.

of enamine prepared from aldehyde **179** and imidazolidinone catalyst **180**. High enantioselectivity for the α -oxyamination alcohol product **181** was obtained in good yield and high enantioselectivity after reduction of the intermediate aldehyde with NaBH₄. The reactions proceeded with good enantioselectivity with a variety of aldehydes. Furthermore, the authors demonstrated the use of catalytic amount of the SET reagent using a co-oxidant (NaNO₂/O₂) without compromising yield and selectivity.

MacMillan and coworkers and Nicolaou *et al.* independently demonstrated asymmetric α -arylation

Scheme 34 Enantioselective allylation via SOMO catalysis.

Scheme 37 Intermolecular α -arylation using SOMO catalysis.Scheme 35 Enantioselective α -oxyamination of aldehyde.Scheme 36 Intramolecular α -arylation using SOMO catalysis.

of aldehydes via SOMO catalysis.^{92–94} As shown in Scheme 36, in the presence of imidazolidinone catalyst **183** and 2.5 equiv of the oxidant $[\text{Fe}(\text{phen})_3]\text{PF}_6$, aryl-tethered aldehyde **182** underwent the designed cyclization process smoothly and gave formyl α -arylation product **184** in 80% yield with excellent enantioselectivity (98% ee). Moreover, a wide variety of aryl and heteroaryl ring systems were applicable in this intramolecular

α -aldehyde arylation reaction. For example, anisole, naphthalene, indole, pyrrole, thiophene, and furan ring systems all function well in the ring-forming reaction.

An intermolecular arylation between aldehyde **177** and pyrrole mediated by catalyst **173** was also reported by MacMillan's group.⁹⁰ The reaction proceeds in good yield and selectivity to furnish the arylated product **185** (Scheme 37).

π -Rich enolsilanes are excellent reagents as “SOMOphiles” in another designed reaction from the MacMillan group that provides access to enantioenriched γ -ketoaldehydes from simple aldehydes (Scheme 38).⁹⁵ Reaction of aldehyde **177** with enol silane **186** using catalyst **173** gave the 1,4-dicarbonyl product **187**. The reaction shows broad scope for both the aldehyde and the enolsilane components.

The 3π -electron radical cation obtained after oxidation of enamines could also be trapped by simple styrene derivatives (Scheme 39). In this reaction, radical addition derived from **177** and **189** to styrene **188** results in a stable benzyl radical (**191**). A cationic intermediate (**192**) is formed after a second SET process. This is trapped by NO_3^- in the reaction mixture to form α -alkyl- γ -nitrate-aldehyde **190** as the product. The reaction described in Scheme 39 showed high enantioselectivity (96% ee) and moderate diastereoselectivity (*syn/anti* = 1 : 3) for the product aldehyde. Furthermore, β -substituted styrene was a competent substrate for SOMO catalysis resulting in the formation of a product with three stereogenic centers.⁹⁶

MacMillan and coworkers have developed a process that provides access to enantioenriched α -vinyl aldehydes. The process involves reaction of an aldehyde **193** with an (*E*)-alkene containing vinyl trifluoroborate salt **194**. The reaction is mediated by an imidazolidinone catalyst and an

Scheme 38 Synthesis of 1,4-dicarbonyl compounds via SOMO catalysis.

Scheme 39 Radical reaction with styrenes via SOMO catalysis.

Scheme 40 α-Vinylation of aldehydes via SOMO catalysis.

oxidant. The product α-vinyl aldehydes **195** are formed in high enantioselectivity as *E*-isomers only (Scheme 40).⁹⁸ More importantly, epimerization and olefin isomerization to an α,β-unsaturated product were not observed under the reaction conditions. A wide variety of aldehydes and alkene components have been examined and enantioselectivities for all these cases were in the range of 89–96%.

MacMillan's group has also investigated the possibility of asymmetric trapping of electrophilic

benzyl radicals with a chiral enamine derived from aldehydes and a chiral amine catalyst (Scheme 41).⁹⁸ In this study, commercially available photocatalyst *fac*-Ir^{III}(ppy)₃ was used to generate benzyl radicals through an SET process using household fluorescent light (see **Synthetic Radical Photochemistry**). The benzyl radical adds to the chiral enamine to form an α-amino radical. The product *fac*-Ir^{IV}(ppy)₃ species formed after the first SET process functions as

Scheme 41 α -Benzylation of aldehydes via SOMO catalysis.

a reductant and transforms the α -amino radical intermediate to an iminium intermediate by a second SET process. This results in recovery of the photocatalyst. The iminium intermediate is hydrolyzed to the product. As shown in Scheme 41, in the presence of a modified imidazolidinone catalyst **197** and photocatalyst *fac*-Ir^{III}(ppy)₃, aldehyde **177** reacts smoothly with 4-(bromomethyl)pyridine to give **198** in high enantioselectivity (90% ee) and high yield. Further investigation showed that electron-deficient aryl and heteroaryl substrates were effective under the same conditions leading to a variety of enantioenriched α -benzylated aldehydes.

Tandem reactions have also been investigated using SOMO catalysis. Using this methodology, multiple bonds can be formed efficiently in an asymmetric manner leading to polycycles. As an example, MacMillan and coworkers reported the cyclization of an unsaturated aldehyde **199** under SOMO catalysis conditions using catalyst **200**. In this reaction, nine contiguous stereocenters are formed in one step including four all-carbon quaternary stereocenters to furnish **201** in 93% ee and excellent yield (Scheme 42).⁹⁹

A highly selective, radical-mediated (4 + 2) coupling of aldehydes and conjugated olefins has also been achieved through asymmetric SOMO catalysis

Scheme 42 Polycyclic product formation via SOMO catalysis.

Scheme 43 Cascade cycloaddition via SOMO catalysis.

(Scheme 43).¹⁰⁰ A radical polar crossover mechanism was proposed wherein olefin addition to transient enamine radical cation and oxidation of the resulting radical furnishes a cation, which is vulnerable to nucleophilic addition. A variety of aromatic aldehydes (**202**) couple to styrenes and dienes to provide cyclic products (**204**) with high chemical efficiency, regioselectivity, and stereoselectivity.

Compared to aldehydes, ketones show lower reactivity under SOMO catalysis. Most of the widely used imidazolidinone catalysts decompose under

oxidative conditions when used in conjunction with ketone substrates. Newly designed imidazolidinone catalysts **207**, **208**, and **209** proved to be stable under oxidative conditions and could be used for reactions with ketones (Scheme 44).¹⁰¹ Using allyltrimethylsilane as the alkylation reagent, allylation of cyclohexanone **205** proceeded enantioselectively in good yield and selectivity to furnish **206** (74–80 and 88–94% ee). Moreover, these new catalysts could also be used in α -enolization and α -homobenzoylation of cyclohexanone in good enantioselectivities.

Scheme 44 Allylation of cyclohexanone via SOMO catalysis.

3.4.2 Chiral Brønsted Acid Catalysis in Radical Reactions

Recently, chiral BINOL-based phosphoric acid analogues **210** have been explored as organocatalysts in a wide variety of synthetic transformations.¹⁰² Among all these types of reactions catalyzed by chiral phosphoric acids, 1,2-addition of nucleophiles to imines has received greater attention from synthetic chemists.¹⁰³ Lee and Kim have investigated reductive radical additions to imine using chiral Brønsted acids as catalysts (Scheme 45).¹⁰⁴ In this study, nontin reagent TTMSS was chosen as radical chain carrier and hydrogen atom source. Phosphoramidate **210** proved to be the optimal catalyst for the radical addition. Under standard radical reaction conditions, primary, secondary, and tertiary alkyl radicals derived from the corresponding alkyl iodides gave 1,2-addition products **212–213** with imine substrate **211**. Although the enantioselectivities were good to high (73–84% ee) for all the reactions, secondary and tertiary alkyl radicals gave low yields and a byproduct from ethyl radical addition was also observed.

Scheme 45 Chiral Brønsted acid-catalyzed radical addition to imine.

3.4.3 Hydrogen Bonding Catalysis in Radical Reactions

In 2004, Bach and coworkers reported the earliest example of a radical reaction using an organic activator. The reaction was an intramolecular radical cyclization followed by enantioselective hydrogen atom transfer mediated by a H-bonding catalyst **215** (Scheme 46).¹⁰⁵ The enantioselectivity for the reductive cyclization of 3-(ω -iodoalkylidene)piperidin-2-ones (**214**) was investigated and the observed selectivity for **216** could reach as high as 84% at -78°C . It should be noted that lower amounts of radical initiator (Et_3B) gave improved enantioselectivities and a large excess of the chiral source **215** (2.5 equiv) was necessary to obtain selectivity. The observed stereochemistry was explained using a model shown in **217**, where the substrate and the chiral reagent form two hydrogen bonds and provide an organized structure for selective H-atom transfer.

Organocatalyst **215** was also used to investigate radical cyclization of 4-(4'-iodobutyl)quinolinone **218** and **220** under similar conditions as described above.¹⁰⁶ When 2.5 equiv of the catalyst **215** was

used, reaction of **218** gave the 6-endo product **219** in good yield and excellent selectivity (99% ee). Interestingly, cyclization of **220** substituted with a *gem*-dimethyl group gave the spirocyclic 5-*exo* product **221** exclusively in good yield and with high enantioselectivity (94% ee).

Scheme 46 Hydrogen bond-mediated asymmetric radical reaction.

Scheme 47 Asymmetric cyclization of 4-(4'-iodobutyl) quinolinones.

Scheme 48 Enantioselective photochemical radical cyclization.

Bach and coworkers modified the hydrogen bonding catalyst **215** and incorporated a benzoyl group that could function as a photon acceptor and evaluated it in radical cyclizations. Ultraviolet irradiation of a mixture of substrate **222** and catalyst **223** induced an electron transfer from the amine to the photoexcited catalyst.¹⁰⁷ Subsequent loss of a

proton from the intermediate radical cation presumably led to an α -aminoalkyl radical, which added intramolecularly to C-4 of the quinolone substrate furnishing **224** (Scheme 48). The reaction gave 70% enantioselectivity and ~64% yield using substoichiometric amount of the catalyst. A stereochemical model for the reaction is shown in **225**.

3.5 Chiral Ligand-Assisted Asymmetric Electron Transfer Reactions

3.5.1 Samarium-Mediated Asymmetric Radical Reactions

Samarium iodide is a versatile reagent that is extensively used in radical chemistry (see **Organic Synthesis Using Samarium Diiodide**). Samarium iodide or samarium metal are excellent SET reagents. There are multiple reviews on the use of samarium iodide in radical reactions.^{108–110} As mentioned before, after SET process, the newly formed samarium(III) species has Lewis acidity that could affect diastereoselectivity in radical reactions. In principle, chirality could be achieved using a chiral ligand in samarium-mediated radical process. Ketyl radicals generated using samarium(II) iodide have found applications in asymmetric transformations. Inanaga and coworkers have applied chiral samarium(II) complex, derived from SmI_2 and (*R*)-BINOL, to promote reductive homo-coupling reaction of β -monosubstituted acrylic acid amides **226** to give the corresponding 3,4-*trans* disubstituted adipamides **227** in high enantioselectivities (up to 85% ee). The yield of **227** in this transformation was rather low and was accompanied by a byproduct **228**. Excess amount of SmI_2 and the chiral ligand were required for obtaining high selectivity.¹¹¹ A model **229** that accounts for the observed selectivity has been proposed (Table 26).

Mikami and Yamaoka¹¹² have investigated asymmetric addition of ketyl radicals to olefins. As shown in Table 27, SmI_2 -mediated reductive coupling of ketones **230** with α,β -unsaturated esters **231** proceeded enantioselectively using 2 equiv of (*R*)-BINAPO **232** as the chiral ligand. The products **233** were formed in good enantioselectivity, but the chemical efficiency was low (<50% yield).

3.5.2 Titanium-Mediated Asymmetric Radical Reactions

Titanium(III) catalysts are also good electron-transfer reagents to generate ketyl radicals

from carbonyl compounds. The enantioselective pinacol coupling of aldehydes has been achieved using a chiral titanium complex as the catalyst. Air-stable catalyst **235** derived from tridentate salen ligand and TiCl₄ could promote the pinacol coupling of *p*-methoxybenzaldehyde **234** to provide the diol **236** in high yield and selectivity (91% ee).¹¹³ A survey of reductants (Mn, Ce, SmI₂, and Zn) suggested manganese to be the ideal one for reactions at -10°C. Electron-deficient benzaldehydes gave poor enantiomeric excesses for the coupling products (Scheme 49).

Titanium(III) catalysts are also excellent electron transfer reagents in reactions with epoxides (see **Epoxides in Titanocene-Mediated and -Catalyzed Radical Reactions**). The general procedure is to combine Ti(IV) with zinc metal to generate Ti(III) *in situ*, which coordinates to the epoxide and carries out an electron transfer to furnish an α -titanoxy radical. This radical intermediate could be reduced by trapping with hydrogen atom or allowed to react further with other radical acceptors. Gansäuer and coworkers have investigated ring-opening reactions of *meso*-epoxides using different chiral titanium catalysts.¹¹⁴ The results showed that *meso*-epoxide **237** in the presence of chiral titanium complex **239** or **240** underwent ring opening to give triol derivatives **238** in good yields and excellent enantioselectivities (74–94%). Importantly, the catalyst loading could

Ph	H	Me	42	66 : 34	89/55
Ph	Me	H	18		63

Scheme 49 Titanium-mediated pinacol formation.

be decreased to as low as 5% without impacting selectivity (Table 28).

The same Ti(III) catalysts were also utilized in the ring opening of cyclic epoxides **241** followed by trapping of the intermediate radical with *t*-butyl acrylate **242** (Scheme 47). The *trans* : *cis* selectivities for the products were greater than 4 : 1 and good enantioselectivities for the *trans* isomer **243** was obtained. Ring size had minimal impact on selectivity (Table 29).¹¹⁵

3.5.3 Oxidative Coupling

SET takes place from metal to the organic substrate in samarium- and titanium-mediated radical

Table 28 Epoxide ring opening using titanocene catalysts.

Entry	R	Catalyst	Yield (%)	ee (%)
1	Et	239	76	93
2	Et	240	72	94
3	<i>n</i> -Pr	240	60	92
4	<i>n</i> -Pr	239	70	91
5	<i>t</i> -Bu	240	68	74
6	<i>t</i> -Bu	239	66	86

reactions. The reverse scenario can also be used in radical reactions via oxidative generation of cationic radical species that can undergo coupling reaction. Asymmetric oxidative coupling has been achieved using a combination of metal with chiral ligands. For example, in the oxidative homo coupling (Scheme 50) of 2-naphthol derivative **244**, chiral 1,5-diaza-*cis*-decalin **245** proved to be an efficient ligand (Scheme 48). When CuI/O₂ was used as the oxidant, the corresponding BINOL derivative **246** could be obtained in high enantioselectivity

Table 29 Epoxide ring opening using titanocene catalysts followed by trapping with an α,β -unsaturated ester.

Entry	<i>n</i>	Catalyst	Yield (%)	ee (%)
1	1	240	69	74
2	1	239	72	81
3	2	240	61	82
4	3	240	65	82
5	3	239	78	80

Scheme 50 Asymmetric oxidative homo coupling via SET process.

(up to 93% ee).^{116–118} Under these conditions, Cu(I) is oxidized to Cu(II) *in situ* due to the presence of oxygen and enters the catalytic cycle.

4 CONCLUSION

In the past 25 years, it is safe to say that radical chemistry has reached its potential and can now compete effectively with ionic chemistry for the installation of C–C and C–X bonds with high enantioselectivity. Radical reactions generally proceed under neutral conditions and show a large functional group tolerance. The need for protecting groups is also minimized during radical reactions. A variety of chiral activators have been utilized for installing stereochemistry in radical reactions. Enantioselective radical reactions mediated by chiral Lewis acids still suffer from large catalyst loading and the need for toxic tin reagents. Organocatalysts have made a significant impact on enantioselective radical chemistry and a good fraction of them can be considered ecofriendly. The future looks very promising for the development of efficient and highly selective radical reactions using a variety of chiral activators with low catalyst loading.

ACKNOWLEDGMENTS

We thank the National Institutes of Health, General Medical Sciences (NIH GM-54656), for support

of our research programs. We also like to thank all the coworkers who have participated in our research program on radical chemistry: Prof Craig Jasperse, Dr Jianguo Ji, Dr Tara Rheault, Dr John Shay, Dr Yasutomi Asano, Dr Jianxie Chen, Mr Justin Sausker, Dr Changjia Zhao, Dr Masayuki Hasegawa, Dr Sukanya Nad, Dr Julien Coulomb, Dr Sunggi Lee, Dr Hiroshi Yanagita, Dr Keisuke Kawashima, and Dr Norihiko Takeda. Yong-Hua Yang would like to thank the Core Synthesis Facility of Center for Protease Research at North Dakota State University for financial support.

Boron in Radical Chemistry

Philippe Renaud

Department of Chemistry and Biochemistry, University of Bern, Bern, Switzerland

1 INTRODUCTION

The tremendous development of radical chemistry has been triggered by the unique properties of tin derivatives that allow the design of a wide range of efficient chain reactions. However, application of this chemistry is severely hampered by the toxicity of triorganotin derivatives. The ability of organoboron compounds to participate in free-radical reactions has been identified since the earliest investigation of their chemistry.¹ Taming the radical reactivity of organoboranes was a slow process but, eventually, it led to an extremely valuable alternative to tin chemistry for a wide range of reactions. The low toxicity of boric acid derivatives that are usually formed at the end of the processes makes this chemistry particularly promising for synthesis and industrial applications can be envisaged. The distinctive properties of boron derivatives make them suitable for the achievement of some unique transformations. The use of organoboranes in radical reactions has been reviewed at several occasions in recent time.^{2–4} This article mainly focuses on recent developments but basic principles and key discoveries are briefly described to give a general picture of the field.

2 REACTIVITY OF ORGANOBORANES

The autoxidation of organoboranes (Scheme 1) is known for a long time to involve radical intermediates.^{5–7} This observation led to the use

of triethylborane as a universal radical initiator operative under a very wide range of reaction conditions (temperature and solvent).^{8,9}

Interestingly, homolytic substitution at boron does not proceed with carbon-centered radicals.¹⁰ However, many different types of heteroatom-centered radicals, for example, alkoxyl radicals, react efficiently with organoboranes (Scheme 2).

Bimolecular homolytic attack by free radicals at boron centers were extensively studied three decades ago.^{11–14} In a typical S_H2 reaction, an oxygen radical may displace an alkyl radical, as shown in Scheme 2. Species **1** has never been observed when R is aliphatic. However, it has been detected in the case of aromatic systems; the intermediate was identified by using laser flash photolysis techniques.¹⁵ Recently, Scaiano reported a theoretical investigation on the reaction mechanism for oxygen-centered radical attack on alkyl- and arylboranes.¹⁶ The model reveals how the mechanism, traditionally considered as an S_H2 reaction, involves instead nucleophilic attack of the oxygen lone pair on the empty boron p orbital. The single electron on the oxygen is not directly involved in the process. However, as a result of a stereoelectronic effect, the bond aligned with the singly occupied molecular orbital (SOMO) is deactivated and the corresponding ligand leaves promptly as a radical species. The overall mechanism can be described as a nucleohomolytic reaction that shares many characteristics with conventional nucleophilic substitution (Scheme 3, model **2**). In the case of triphenylborane, the intermediate **3** was located by DFT calculations

Scheme 1 Autoxidation of organoboranes.

Scheme 2 Reactivity of trialkylboranes toward carbon- and heteroatom-centered radicals.

Scheme 3 Proposed transition state (**2**) and intermediate (**3**) in the homolytic substitution of trimethylborane and triphenylborane by a methoxyl radical.

in agreement with experimental observations.¹⁵ The geometry at the boron center is a distorted tetrahedron, with a trigonal pyramidal component, because of the slightly stretched bond of the leaving phenyl group.

3 ORGANOBORANES AS RADICAL INITIATORS

Utimoto and Oshima were the first to apply the reaction of triethylborane with oxygen to initiate radical reactions (see **Overview of Radical Initiation**).^{8,17} The system Et₃B–O₂ offers over classical initiators the great advantage of being efficient even at low temperature (–78 °C). This aspect proved to be particularly important for the development of stereoselective radical reactions and for radical reactions involving thermally unstable adducts or products. Review articles describing the use of triethylborane as a radical initiator have appeared.^{3,9} A few selected examples, mainly from recent publications, are presented to highlight the borane initiation procedure. The use of trialkylboranes, such as tributylborane, is of growing importance in the field of polymer chemistry.¹⁸ Applications in unexpected fields, such as dental adhesives, have been reported.¹⁹

3.1 Reduction of Halides and Related Compounds

Evans reported the cyclization of acyl radicals to vinylogous carbonates in the presence of (TMS)₃SiH (TMS = Me₃Si). By using Et₃B–air initiation rather than azobisisobutyronitrile (AIBN), the *cis*-oxepanones are obtained in higher stereoselectivities and yields. Interestingly, the decarbonylation of the intermediate acyl radical is suppressed (Scheme 4).²⁰ Inoue and Hiram applied a similar acyl cyclization strategy using tributylgermanium hydride for the stereoselective preparation of polycyclic ethers related to ciguatoxin and brevetoxin.²¹

The use of acid-labile radical precursors is perfectly compatible with this initiation procedure

Scheme 4 Reductive cyclizations with silanes.

Scheme 5 Ueno–Stork cyclization involving an acid-sensitive allylic ether.

Scheme 6 Key cyclization in the synthesis of ciguatoxin CTX3C.

as shown by the Ueno–Stork cyclization used as a key step in the (+)-merrillactone synthesis of Inoue (Scheme 5).²²

Another spectacular example of the efficiency of the Et_3B –air method is depicted in Scheme 6. This highly stereoselective cyclization of an O,Se-acetal is the key reaction of a practical synthesis of ciguatoxin CTX3C reported recently by Yamashita *et al.*²³

Interestingly, Et_3B –air initiation can be performed in aqueous solution.²⁴ A wide range of aryl and alkyl halides are reduced in water by water-soluble organosilanes using Et_3B –air initiation.²⁵ Tin-free radical reduction by organophosphites and phosphinic acid can also be initiated by Et_3B –air.²⁶ For instance, radical cyclizations using phosphinic acid neutralized with sodium carbonate and Et_3B –air as a radical initiator in aqueous ethanol are reported.²⁷ A similar stereoselective cyclization of a β -alkoxyacrylate with 1-ethylpiperidinium

hypophosphite (EHP) at room temperature is described by Lee (Scheme 7).²⁸

3.2 Addition of RX-H to Alkenes and Alkynes

Tris(trimethylsilyl)silane (see **Silanes as Reducing Reagents in Radical Chemistry**),^{29,30} thiols,³¹ germanes,^{32–34} and gallium hydride³⁵ add easily to terminal alkynes in the presence of Et_3B –air.³⁶ The addition of hypophosphites to alkenes under Et_3B initiation is also reported.³⁷ Piettre described recently the addition of diethylthiophosphite to alkenes leading to the formation of thiophosphonates (Scheme 8).³⁸ Interestingly, this reaction can be used for cyclization of dienes and ring opening of strained alkenes such as α -pinene. Parson prepared an alkenylthiophosphonate by reaction of a chiral thiophosphite with phenylacetylene.³⁹

Scheme 7 Phosphinic-acid-mediated radical cyclization.

Scheme 8 Addition of diethylthiophosphite to alkenes.

Scheme 10 Lactone synthesis via iodine atom transfer, influence of water.

3.3 Atom-Transfer and Related Processes

3.3.1 Iodine Atom Transfer

Triethylborane proved to be a good initiator for iodine atom-transfer reactions (see **Halogen and Chalcogen Transfer Chemistry**).^{24,40,41} The ethyl radical, issued from the reaction of triethylborane with molecular oxygen, can abstract an iodine atom from the radical precursor to produce a radical $R^\bullet$ that enters into the chain process. The iodine exchange is fast and efficient when $R^\bullet$ is more stable than the ethyl radical. The efficiency of the whole process is also probably due to the high reactivity of Et_3B toward molecular iodine that results in an efficient removal of undesirable traces of I_2 in the reaction mixture. A similar effect has been put forward to explain the role of hexamethyl- and hexabutylditin in radical-mediated iodine atom transfer.⁴²

Et_3B -induced addition of perfluoroalkyl iodides,^{43,44} α -iodoesters,⁴⁵ α -iodoamides,⁴⁶ α -iodonitriles,⁴⁵ and simple alkyl iodides⁴⁷ to alkenes and alkynes are reported. Interestingly, these reactions are also performed with success in aqueous media^{24,48,49} demonstrating further the ability of Et_3B to act as an initiator in water (Scheme 9).⁵⁰

Triethylborane is also an excellent initiator for intramolecular iodine atom-transfer reactions. For example, cyclization of the propargyl α -iodoacetal gives the corresponding bicyclic vinyl iodide in high yield.⁴⁷ Allyliodoacetamide and allyliodoacetate (Scheme 10) cyclize cleanly under Et_3B -air initiation. In the case of the ester, the reaction has to be run in refluxing benzene in order to allow Z/E -ester isomerization before cyclization.^{51,52} No

Scheme 9 Iodine atom transfer in water.

trace of cyclized product is detected when the reaction is carried out at room temperature. Interestingly, by running the same reaction in water, Oshima obtained the desired lactone in 78% yield.⁴⁸ It was suggested that water facilitates the Z/E isomerization. Efficient preparation of medium- and large-ring lactones in water is reported.^{48,49}

Examples of tandem intermolecular addition–cyclization under iodine atom-transfer conditions are reported.^{47,50} Et_3B -induced radical cascade reactions with 1,5-enynes and 1,5-dienes are applied to the synthesis of dioxatriquinanes and tricyclic glucoconjugates.^{53,54} Some of these elegant cascade cyclizations are performed under mild conditions at -50°C . Miyabe and Takemoto investigated the enantioselective formation of lactams by an addition–cyclization process involving hydroxamates and chiral Lewis acids.^{55,56}

Taguchi reported annulation reactions using acyclic and cyclic N -tosylated iodomethylaziridines.⁵⁷ The reaction with electron-rich alkenes, such as silylenol ethers, proceeds smoothly as illustrated in Scheme 11.

Silylenol ethers are also utilized as a trap for electrophilic radicals derived from α -haloesters⁴⁵ or perfluoroalkyl iodides.⁵⁸ They afford the α -alkylated ketones after acidic treatment of the intermediate silylenol ethers. Similarly, silyl ketene acetals are converted into α -perfluoroalkyl esters upon treatment with perfluoroalkyl iodides.^{58,59} The Et_3B -air initiated diastereoselective trifluoromethylation^{60,61} (Scheme 12) and (ethoxycarbonyl) difluoromethylation^{62,63} of lithium enolates derived from N -acyloxazolidinones were achieved. More recently,

Scheme 11 Preparation of pyrrolidine derivatives via annulation with iodomethylaziridine derivatives.

Scheme 12 Trifluoromethylation of a lithium enolate.

Mikami succeeded in the trifluoromethylation of ketone enolates.⁶⁴

3.3.2 Bromine Atom Transfer

Bromides are less reactive than the corresponding iodides in atom-transfer processes (see **Halogen and Chalcogen Transfer Chemistry**). However, activated bromides such as diethyl bromomalonate⁴⁵ and bromomalonitrile react with olefins under Et_3B –air initiation.⁶⁵ Kharasch-type reactions of bromotrichloromethane with alkenes are also initiated by Et_3B –air.⁵⁰ A remarkable Lewis acid effect was reported by Porter. Atom-transfer reactions of an α -bromooxazolidinone amide with alkenes is strongly favored in the presence of Lewis acids such as $\text{Sc}(\text{OTf})_3$ or $\text{Yb}(\text{OTf})_3$; this reaction was employed for the diastereoselective alkylation of chiral oxazolidinone derivatives.⁶⁶ Yang reported a similar effect with bromomalonates⁶⁷ and was able to run an enantioselective cascade process involving a bromine atom transfer at -78°C (Scheme 13).⁶⁸ Interestingly, Oshima reported that bromine atom transfers take place at room temperature in ionic liquid media.⁶⁹

3.3.3 Chlorine Atom Transfer

Radical [3 + 2] annulation involving *N*-allyl-*N*-chlorotosylamide provides a route to pyrrolidine derivatives (Scheme 14).⁷⁰ The reaction of *N*-chlorosulfonyl derivatives with enol ethers initiated by Et_3B has also been reported.⁷¹

Scheme 13 Enantioselective cascade process involving a bromine atom transfer.

Scheme 14 Pyrrolidine preparation via a radical [3 + 2] annulation.

3.3.4 Phenylselenium Transfer

The transfer of phenylselenanyl group initiated by the system Et_3B –air works very efficiently in the presence of Lewis acids and promising enantioselectivities has been obtained in the presence of a box ligand (Scheme 15).⁷²

Scheme 15 Enantioselective cascade process involving a phenylselenanyl group transfer.

Scheme 16 Addition of α -xanthate- α -fluoroacetate to dihydrofuran.

Scheme 17 Stereospecific styrylation reaction with an alkenylindium.

3.3.5 Xanthate-Transfer Reactions

The transfer of xanthates is a powerful method for C–C bond formation developed by Zard (see **Xanthates and Related Derivatives as Radical Precursors**).⁷³ Initiation is usually performed with the cheap and easy to handle dilauroyl peroxides (DLPs) at temperatures above 80 °C. When a lower temperature is desired, the use of Et_3B –air provides good results.^{74–77} For instance, the addition of xanthates to dihydrofuran affords the desired adducts in good yields when the reaction is performed in dichloromethane (Scheme 16).⁷⁵ Addition of xanthates derived from ketones requires carefully controlled reaction conditions to avoid the formation of a transient boron enolate leading to simple reduction of the xanthate.⁷⁶ A xanthate-transfer process initiated by Et_3B –air has been employed to perform an elegant addition–substitution sequence leading to selenochromanes.⁷⁸

3.4 Alkenylation, Allylation, and Related Processes

Oshima reported radical alkenylation and allylation of α -halo carbonyl compounds under mild conditions by utilizing vinyl and allyl organometallic radical traps and Et_3B as a radical initiator.^{35,79–81}

Scheme 18 Perfluoroalkylation of ketones via germynol ethers.

Styrylation reaction shows retention of the stereochemistry of the starting alkenylindium (Scheme 17).

Germynol ethers react with perfluoroalkyl iodides under Et_3B initiation to give α -perfluoroalkyl ketones. The intermediate radical adduct decomposes readily via β -elimination and provides the α -perfluoroalkyl ketone and a trialkylgermyl radical as a chain carrier (Scheme 18).⁵⁸

Kim reported a metal-free approach for the α -alkylation of ketones via *N*-siloxyenamine (Scheme 19).⁸² In this reaction, Et_3B is supposed to act as an initiator since fragmentation of the intermediate radical adduct affords a siloxy radical that undergoes a 1,2-phenyl shift to produce a silyl

Scheme 19 α -Alkylation of ketones with an *N*-siloxyenamine.

Scheme 20 Radical phenylation of an α -iodoester.

radical that propagates the chain. However, since 0.5 equivalent of Et_3B is used, the efficiency of the chain process is questionable and Et_3B may well be acting as a chain transfer reagent (see Section 5).

3.5 Arylation Processes

Intramolecular arylation processes initiated by Et_3B –air system are reported. They involve a radical 1,4-aryl migration from tin to a carbon.⁸³ An intermolecular α -arylation of a ketone with phenylindium dichloride is reported. The reaction requires the presence of triethylborane (Scheme 20). A mechanism involving an addition–fragmentation process may be operative but an electron transfer process cannot be ruled out.

Miranda reported the Et_3B -mediated arylation of ester and amide α -xanthates with pyrrole and indole derivatives in the presence of iron(II) sulfate (Scheme 21). The reaction is not a chain process and it requires a stoichiometric amount of the initiator. The iron(II) salt is probably oxidized to iron(III) by borane peroxides that insures rearomatization via oxidation of the transient radical adduct.

4 ORGANOBORON COMPOUNDS AS A SOURCE OF C-CENTERED RADICALS

Radicals generated from diverse organoboron derivatives can be used for carbon–carbon and carbon–heteroatom bond formation. Efficient chain reactions have been observed with trialkylboranes

and alkylcatecholboranes. More stable organoboron derivatives, such as boronic acid and trifluoroborates, can also be used as a source of radicals under oxidative conditions.

4.1 Trialkylboranes

4.1.1 Trialkylboranes in Conjugate Addition

One of the first synthetic application of organoboranes in radical chemistry is the conjugate addition to enones (Scheme 22) and enals reported by Brown.^{84–87} Addition to β -substituted enones and enals are not spontaneous and initiation with the oxygen,⁸⁸ diacetyl peroxide,⁸⁹ or under irradiation⁸⁹ is necessary.

Brown proposed a mechanism where the enolate radical resulting from the radical addition reacts with the trialkylborane to give a boron enolate^{90,91} and a new alkyl radical that can propagate the chain (Schemes 23).⁸⁷ Water present in the system hydrolyzes the boron enolate and prevents degradation by undesired free-radical processes involving the enolate. This hydrolysis step is essential when alkynones⁹² and acrylonitrile⁸⁴ are used as radical traps since the resulting allenes or keteneimines react readily with radical species. On the basis of the spectroscopic evidences, Maillard and Walton proposed that the reaction of triethylborane with radical traps, such as methyl vinyl ketone (MVK), acrolein, and 3-methylbut-3-en-2-one, involves complexation of the trap by the Lewis acidic borane prior to conjugate addition.⁹³

Scheme 22 The Brown conjugate addition.

Scheme 21 Radical arylation of axanthate.

Scheme 23 Brown mechanism for the conjugate addition of organoboranes to methyl vinyl ketone.

The reaction between trialkylboranes and enones has found some interesting synthetic applications. An example is the preparation of prostaglandin precursors from *exo*-methylene cyclopentanone, generated *in situ* from a Mannich base. After dehydrogenation, a second conjugate addition of trioctylborane is used to introduce the ω -chain (Scheme 24).⁹⁴ Radical addition to benzilidene Meldrum's acid⁹⁵ and benzilidenemalonitrile⁹⁶ have been reported. Simple unsaturated esters, lactones, and amides do not react under these conditions because of the inefficiency of the chain propagation. Initiation of the chain reaction using *tert*-butylperoxide under microwave irradiation provides interesting opportunities for scale-up.⁹⁷

A serious drawback of the trialkylborane reactions is that only one of the three alkyl groups is transferred. The more sophisticated *B*-alkylboracyclanes have been introduced to overcome this limitation.^{98,99} However, this method, referred later as the Brown–Negishi reaction, is not suitable for primary alkyl radicals (yield < 35%)

and for traps substituted at the β -position. Similar results are obtained with cyclohexyldiethylborane (easily prepared from Et₂BH and cyclohexene). The efficient addition to MVK is possible. However, the same limitation as the Brown–Negishi reaction was observed with other radical traps.¹⁰⁰ Recently, the use of alkyldiphenylborane and alkyldimethylborane was reported for addition to benzoquinone.¹⁰¹

Several attempts to take advantage of the intermediate boron enolate to achieve tandem conjugate addition–aldol reaction are published.¹⁰² Chandrasekhar reported the addition of triethylborane to MVK followed by the *in situ* trapping of the enolate by reaction with benzaldehyde (Scheme 25).¹⁰³

Toru investigated the stereoselectivity of the conjugate addition of trialkylboranes to 2-arylsulfinylcyclopentenones.^{104–107} Excellent stereocontrol is achieved with different alkyl radicals (Scheme 26). The lack of diastereoselectivity and a competitive Pummerer rearrangement has limited the synthetic potential of this reaction in acyclic systems.¹⁰⁸

The reaction of trialkylboranes with 1,4-benzoquinones to give 2-alkylhydroquinones in quantitative yield was the first reaction of this type occurring without the assistance of a metal mediator.^{109,110} An ionic mechanism was originally proposed but rapidly refuted since the

Scheme 25 Tandem conjugate addition–aldol reaction.

PTT = Phenyl trimethylammonium perbromide

Scheme 26 Stereoselective addition to 2-arylsulfinylcyclopentenones.

Scheme 27 Addition of alkyl radicals to quinones using trialkylboranes.

reaction is inhibited by radical scavengers such as galvinoxyl and iodine.¹¹¹ This procedure is in many cases superior to the more widely used organometallic additions. Primary and secondary alkyl radicals afford the addition products in high yield (Scheme 27).¹¹²

4.1.2 Trialkylboranes in Addition to Imines

Intramolecular addition of trialkylboranes to imines and related compounds have been reported and the main results are part of review articles.^{113,114} Addition of ethyl radicals generated from Et₃B to aldimines affords the addition products in fair to good yield but low diastereocontrol.¹¹⁵ Similar reactions with aldoxime ethers,¹¹⁶ aldehyde hydrazones,¹¹⁶ and *N*-sulfonylaldimines¹¹⁷ and ketimines¹¹⁸ are published. Addition of triethylborane to 2*H*-azirine-3-carboxylate derivatives was investigated¹¹⁹ and Somfai extended this reaction to the addition of different alkyl radicals generated from trialkylboranes to a chiral ester of 2*H*-azirine-3-carboxylate under Lewis acid activation with CuCl (Scheme 28).¹²⁰ Multicomponent reactions are also possible.¹²¹

Naito reported a radical addition to nitrones that occurs with high stereocontrol (Scheme 29).¹²²

Interestingly, most of the reactions reported with imines and related products such as oximes, oxime

Scheme 28 Addition of trialkylboranes to a chiral ester of 2*H*-azirine-3-carboxylate under Lewis acid activation with CuCl.

Scheme 29 Addition of triethylborane to nitrones.

ethers, hydrazones, and nitrones can be performed in aqueous media.¹²³

4.1.3 Trialkylboranes in β -Fragmentation Processes

Brown and Suzuki showed that the treatment of trialkylboranes with ethenyl- and ethynylloxiranes in the presence of a catalytic amount of oxygen, affords the corresponding allylic or allenic alcohols (Scheme 30). The mechanism involves addition of alkyl radicals to the unsaturated system leading to 1-(oxiranyl)alkyl and 1-(oxiranyl)alkenyl radicals followed by rapid fragmentation to give alkoxy radicals that finally complete the chain process by reacting with the trialkylborane.^{124–126}

According to Yao, the free-radical substitution of β -nitrostyrene (2-nitroethenylbenzene) by trialkylboranes provides *E*-alkenes.¹²⁷ It involves a radical addition to the β -position (α to the nitro group) followed by fragmentation of NO₂[•]. Nozaki reported the reaction of trialkylboranes with styrylsulfoxides and sulfones. Alkyl radicals generated from trialkylboranes add at the β -position of β -styrylsulfoxides and sulfones (α - to the sulfur atom). The resulting radicals fragment and deliver the β -styryl adducts.¹²⁸ Interestingly, the sulfoxides eliminate very rapidly leading to partial retention of the olefin configuration.

Scheme 30 Reaction of trialkylboranes with ethenyl- and ethynyloxiranes.

4.2 B-Alkylcatecholboranes

B-Alkylcatecholboranes have been introduced in order to circumvent the lack of selectivity in the cleavage of trialkylboranes and they proved to be an excellent source of alkyl radicals. They are extremely sensitive toward oxygen and they react readily with alkoxy radicals. Davies and Roberts demonstrated by electron spin resonance (ESR) that a perboranyl radical intermediate resulting from the complexation of *B*-methylcatecholborane with the alkoxy radical is involved in the substitution reaction.¹²⁹ Interestingly, this intermediate is stabilized by delocalization onto the aromatic ring (Scheme 31).

B-Alkylcatecholboranes are more reactive than trialkylboranes and they are easily prepared from olefins via hydroboration with catecholborane with or without a catalyst. However, the most attractive

feature of *B*-alkylcatecholboranes is the possibility to generate selectively one alkyl radical from an olefin. Indeed, reaction of *B*-alkylcatecholboranes with a heteroatom-centered radical leads exclusively to alkyl radicals since the cleavage of B–X and B–O bonds are reversible (Scheme 32).¹³⁰

4.2.1 B-Alkylcatecholboranes in Conjugate Additions

A modified version of the Brown–Negishi reaction using *B*-alkylcatecholboranes is reported.¹⁰⁰ This method is based on a simple one-pot procedure involving the hydroboration of various substituted alkenes with catecholborane, followed by treatment with catalytic amount of oxygen/*N,N'*-dimethylpropyleneurea (DMPU)/water and a radical trap. Efficient radical additions to α,β -unsaturated ketones and aldehydes are

Scheme 31 Reaction of *B*-methylcatecholborane with alkoxy radicals.

Scheme 32 Irreversible formation of alkyl radicals from *B*-alkylcatecholboranes.

Scheme 33 *B*-Alkylcatecholborane-mediated addition of organoboranes to enones.

described. Primary alkyl radicals are efficiently generated by this procedure and the reaction was employed for a 0.3-mol scale synthesis of the γ -side chain of (–)-perturasinic acid (Scheme 33).¹³¹ The reaction is also amenable to radical addition to β -substituted enones and enals as well as to cyclization and annulation reactions.¹⁰⁰

The addition of *B*-alkylcatecholboranes to quinones was investigated.¹³² Good yields of the expected conjugate addition products are obtained with primary and most secondary radicals. However, hindered secondary radicals and tertiary alkyl radicals afford an unexpected product resulting from a radical addition to the oxygen atom of the quinone (Scheme 34).

The modified Brown–Negishi reaction with *B*-alkylcatecholborane (Scheme 33) is mostly limited to enones and enals. Other radical traps such as unsaturated esters, amides, and sulfones fail to react under these conditions. This failure was interpreted as a consequence of an inefficient reaction of the radical adduct and *B*-alkylcatecholboranes. The use of a chain transfer reagent, which is able to convert a carbon-centered radical into an oxygen-centered radical, allows solving this problem. The Barton carbonate PTOC-OMe (PTOC, pyridine-2-thione-*N*-oxycarbonyl)^{133,134} proved to be an excellent radical chain transfer reagent (Scheme 35).¹³⁵ Interestingly, the same reagent is an excellent radical initiator under irradiation with a standard 150-W tungsten lamp. The PTOC-OMe is a stable reagent easily obtained by the reaction

Scheme 35 Barton carbonate PTOC-OMe, a radical chain transfer reagent able to convert a C-centered radical into an O-centered radical.

of the commercially available sodium salt of *N*-hydroxypyridine-2-thione with methyl chloroformate. A related strategy has been developed by Dalko and Cossy using the Barton ester PTOC-Ph as chain transfer reagent.¹³⁶

In a preliminary study, *in situ* generated *B*-alkylcatecholboranes were allowed to react with PTOC-OMe under irradiation with a standard 150-W lamp. The *S*-pyridyl products coming from primary, secondary, and tertiary alkyl radicals were isolated in moderate to good yields.¹³⁵ On the basis of these initial results, a procedure for conjugate addition to various activated alkenes was developed. A one-pot procedure involving hydroboration of an alkene with catecholborane followed by irradiation in the presence of 5 equivalents of an activated alkene and 3 equivalents of the chain transfer reagent PTOC-OMe was developed (Scheme 36).¹³⁵ In contrast to the tin hydride-mediated reaction (Giese reaction),¹³⁷ no slow addition of the chain carrier is necessary.

Scheme 34 Addition of *B*-alkylcatecholboranes to quinones: C- versus O-addition.

Scheme 36 PTOC-OMe-mediated conjugate addition of *B*-alkylcatecholborane to activated alkenes.

B-Alkylcatecholboranes, prepared by rhodium(I)-catalyzed hydroboration of alkenes, are suitable radical precursors for conjugate addition to activated olefins. This procedure is particularly useful for the control of the regio- and chemoselectivity of such tandem processes.¹³⁸ A one-pot enantioselective hydroboration–radical conjugate addition was successfully performed. For example, the reaction between norbornene and methyl methacrylate as radical trap affords the product of conjugate addition in 68% yield and 85% enantiomeric excess (after desulfurization) (Scheme 37). The rhodium-catalyzed hydroboration also opens the way to cyclization reactions starting from dienes.¹³⁹

A one-pot procedure involving radical conjugate addition of *B*-alkylcatecholboranes to enones followed by intramolecular aldol reaction was reported recently.¹⁴⁰ This reaction was used to prepare

stereoselectively monocyclic and bicyclic products with up to four contiguous stereogenic centers (Scheme 38).

4.2.2 *B*-Alkylcatecholboranes in β -Fragmentation Processes

Radical allylation of *B*-alkylcatecholboranes using easily available allylsulfones has been described.^{141–143} By using phenylsulfones, the fragmentation produces a stable phenylsulfonyl radical that reacts with *B*-alkylcatecholborane to sustain the chain reaction (Scheme 39). The allylated products are obtained in satisfactory to excellent yields by using only 1.2 equivalents of the allylsulfones with primary, secondary, and tertiary alkyl radicals. Many different types of allylic sulfones bearing an ester group, a sulfonyl group, and a bromine atom react equally well. The whole transformation represents formally a reductive allylation or hydroallylation of alkenes.

An extension of this reaction, that is, the coupling of *B*-alkylcatecholboranes with ethyl 2-(benzenesulfonylamino)acrylate is reported (Scheme 40).¹⁴⁴ In this reaction, fragmentation of an *N*-SO₂Ph bond is taking place during the propagation step. Using this procedure, various α -ketoesters (alkylated pyruvates) were prepared

Scheme 37 Control of the enantioselectivity via rhodium(I)-catalyzed hydroboration.

Scheme 38 *B*-Alkylcatecholborane-mediated tandem radical conjugated addition-aldol cyclization.

Scheme 39 Alkylation of *B*-alkylcatecholboranes with allylsulfones.

Scheme 40 Alkylation of ethyl pyruvate via reductive coupling of alkenes and ethyl 2-(benzenesulfonylamino)acrylate.

in a straightforward manner. It also demonstrates the generality of the radical-mediated C–C bond formation starting from organoboranes and allylicbenzenesulfonyl derivatives.

The cascade conjugate addition–allylation takes place efficiently when a good matching of polarity of the two radical traps is provided. For instance, addition of the primary radical generated from β -pinene to a mixture of phenyl vinyl sulfone and 2-methylallyl phenyl sulfone affords the product of addition–allylation in good yield (Scheme 41).¹⁴⁵

The allylation process was extended to several other related reactions that take advantage of the β -fragmentation of arenesulfonyl radicals. For instance, *B*-alkylcatecholboranes prepared *in situ* by hydroboration of olefins with catecholborane, undergo efficient coupling reactions with vinyl and alkynylsulfones. This procedure was extended to

formylation and cyanation reactions of organoboranes (Scheme 42).¹⁴⁶

4.2.3 Oxygenation, Halogenation, and Chalcogenation of *B*-Alkylcatecholboranes

Owing to the specificity of radical processes (unusual rearrangements, mildness of the reaction conditions), radical hydroxylation of organoboranes represents an interesting alternative to the classical oxidative workup to convert alkenes into alcohols. The conversion of *B*-alkylcatecholboranes, prepared by hydroboration of the corresponding alkenes, is easily performed by treatment with 2 equivalents of TEMPO (2,2,6,6-tetramethylpiperidine-*N*-oxyl), a stable persistent radical (see **Nitroxides in Synthetic Radical Chemistry**),¹⁴⁷ or by treatment with

Scheme 41 Cascade addition–allylation.

Scheme 42 Vinylation, alkynylation, formylation, and cyanation of *B*-alkylcatecholboranes generated *in situ* from alkenes.

Scheme 43 Oxygenation of *B*-alkylcatecholborane using TEMPO.

oxygen. The reaction with TEMPO affords in good to excellent yield the corresponding alkoxyamines (Scheme 43).^{147,148} The first equivalent of TEMPO is used to generate the alkyl radical from the organoborane, the second equivalent is acting as a radical trap to form an alkoxyamine that can be reduced using standard methods to the desired alcohol. Studer reported the use of this reaction with various nitroxides for chemical modification of macromolecules containing multiple double bonds

such as poly(butadiene) and of perallylated polyglycerol.¹⁴⁹

This reaction was also used for a conjugate addition–alkoxy amination process.¹⁴⁸ Very recently, Studer described the beneficial use of a Lewis acid ($\text{MgBr}_2 \cdot \text{Et}_2\text{O}$) for this reaction (Scheme 44).¹⁵⁰ This chemistry was used to prepare macro(alkoxyamines) that are initiators of polymerization.

Interestingly, the generation of α -carbonyl radicals from catecholboron ketone enolates by reaction with TEMPO is also possible. The boron enolates

Scheme 44 Formation of α -(aminyl)oxyketones via radical addition–alkoxy amination.

Scheme 45 Generation of radicals from boron enolates.

Scheme 46 Tandem enantioselective conjugate addition–radical alkoxyamination.

are readily obtained via reduction of linear enones with catecholborane or via “transmetalation” of silylenol ethers and zinc enolates with chlorocatecholborane. *In situ* trapping of the α -carbonyl radicals with TEMPO provided the corresponding alkoxyamines in high yields (Scheme 45). An *in situ* generated enantiomerically enriched chiral boron enolate reacted with TEMPO with very good diastereoselectivity (Scheme 46). Application of this chemistry for polymerization of vinyl ketones has been recently reported.¹⁵¹

The reaction of tetranitromethane with *B*-alkylcatecholboranes leads to the formation of unusual dinitrooxime ethers (Scheme 47).¹⁵² The mechanism involves an extremely fast addition of alkyl radicals to tetranitromethane. The substitution of one of the nitro groups by nucleophiles such as secondary amines, halogens, and styrene, and by radicals generated from *B*-alkylcatecholboranes is reported.

Scheme 47 Reaction of *B*-alkylcatecholborane with tetranitromethane.

The hydroboration of alkenes with catecholborane was used to develop an efficient formal anti-Markovnikov addition of HX (X = Cl, Br, I, SR, and SeR) to olefins (Scheme 48).¹⁵³ The conversion of the intermediate *B*-alkylcatecholboranes to the corresponding halides, sulfides, and selenides is based on a common process, that is, generation of a radical from the alkylborane followed by abstraction of a heteroatom from an aromatic sulfonyl reagent. The mildness of the reaction conditions is well illustrated by the preparation of iodoalkanes. Despite the notorious reactivity of iodoalkanes under radical reactions, no degradation product is observed.

Scheme 48 Halogenation and chalcogenation of *B*-alkylcatecholboranes.

4.3 Modified *B*-Alkylcatecholboranes

In order to facilitate the separation of the final products from catechol derivatives generated during the workup procedure, a modified system involving dihydroxytetrahydroisoquinoline instead of catechol was used.¹⁵⁴ The desired organoborane is prepared *in situ* by hydroboration with BH₃·Me₂S followed by reaction of the monoalkylborane with the modified catechol. The modified alkylcatecholborane can be used in all previously reported radical reactions. Interestingly, the catechol residues are easily eliminated by simple extraction under acidic conditions. This reaction is particularly useful to run radical addition to benzoquinones since the separation of catechol from product hydroquinones is problematic (Scheme 49).

4.4 Boronic Acids and Derivatives

The oxidation of arylboronic acids offers an interesting approach for the generation of aryl radicals. Demir reported the preparation of biaryls resulting

Scheme 50 Mn(III)-assisted synthesis of biaryls.

from the oxidation of arylboronic acid by Mn(III) acetate in benzene or thiophene (Scheme 50).^{155,156}

Studer extended this work to intermolecular addition to alkenes¹⁵⁷ and observed products that resulted from double olefin addition followed by aromatic substitution leading to tetrahydronaphthalene derivatives (Scheme 51). In the presence of oxygen, monoaddition followed by hydroxylation occurs (Scheme 52).

Fensterbank reported the oxidation of the organotrifluoroborate by copper(II) salts or by the Dess–Martin periodinane (DMP) generates alkyl radicals that are either trapped by the excess of TEMPO or by radical traps such as MVK (Scheme 53).¹⁵⁸

A ruthenium-catalyzed coupling reaction of propargylic alcohols via hydroboration with pinacolborane was described. Its mechanism may possibly involve the formation of radicals via an oxidative process.¹⁵⁹

5 ORGANOBORANES AS CHAIN TRANSFER REAGENTS

An important application of organoboranes in radical chemistry is their use as chain transfer reagents.

Scheme 49 Modified *B*-alkylcatecholborane for facilitated purification.

Scheme 51 Synthesis of tetrahydronaphthalene derivatives.

Scheme 52 Oxidative radical hydroxyarylation.

Scheme 53 Generation of radicals from potassium organotri-fluoroborates.

Chain transfer reagents are used when the chain reaction between the radical precursor and the radical trap cannot proceed owing to an unfavorable step. Alkyl radicals generated from the organoboranes are not involved in product formation but they serve to produce the radicals that lead to products. In contrast to reactions where the borane acts as an initiator, a stoichiometric amount of the organoborane is necessary for the reaction to

go to completion. This is best illustrated by the cyclization of alkyl radicals onto aldehydes reported by Malacria (Scheme 54).¹⁶⁰ Upon reaction with the alkoxyl radical, Et₃B generates an ethyl radical that can propagate the chain. In the absence of Et₃B, the alkoxyl radical would not be able to propagate the chain and the reaction would either stop or lead to side products. In this example, the reactive alkyl radical is generated via an iodine atom-transfer process. Reaction is classified here according to the type of reaction and iodine or hydrogen atom transfer used for the generation of the reactive radical.

5.1 Via Iodine Atom Transfer

Bertrand *et al.*^{113,161} and Naito^{114,116} reported the use of triethylborane for the tin-free addition of alkyl iodides to imines. This reaction was extended to 2*H*-azirine-3-carboxylates.^{119,120} Enantioselective radical additions to *N*-acyl hydrazones using triethylborane as chain transfer reagent are reported by Friestad. Enantiomeric excesses up to 95% are

Scheme 54 Triethylborane as a chain transfer reagent for the cyclization of iodoaldehydes.

Scheme 55 Enantioselective addition to *N*-acyl hydrazones.

obtained in the presence of copper(II)-bisoxazolines Lewis acid (Scheme 55).¹⁶² Enantioselective cyclizations onto oxime ethers were examined by Miyabe and Takemoto.^{56,163}

Tandem processes mediated by triethylborane involving conjugate addition of alkyl iodides to enones followed by aldol reaction are reported.¹⁰² A tandem process involving addition of an isopropyl radical to an α,β -unsaturated oxime ether affords an azaenolate intermediate that reacts with benzaldehyde in the presence of trimethylaluminum. The aldol product cyclizes to afford an isopropyl-substituted γ -butyrolactone in 61% overall yield (Scheme 56).¹⁶⁴ Triethylborane is acting as a chain transfer reagent that delivers the azaenolate necessary for the aldolization process. A related hydroxyalkylation process involving oxygenation of the intermediate azaenolate was reported by Myata and Naito.¹⁶⁵

Landais reported the efficient synthesis of piperidinone through a radical cascade mediated by Et_3B (Scheme 57).^{166,167}

Scheme 57 Radical cascade leading to fused bicyclic piperidinones.

Alkenylation of alkyl iodides with β -nitrostyrene derivatives was reported.¹⁶⁸ The reaction is, however, not strictly a chain process since a stoichiometric amount of oxygen is necessary to run the reaction. The radical $\text{NO}_2^\bullet$ is presumably not sufficiently reactive toward triethylborane to sustain the chain process. A similar situation is occurring during the Et_3B -mediated radical carboazidation of alkenes.¹⁶⁹ This efficient process is complete in 1 hour at room temperature in an open to air reaction vessel but an excess of triethylborane (3 equiv) is required to obtain good yields. This may be an indication that the chain process, more precisely the reaction between the benzenesulfonyl radical and Et_3B , is not efficient. Recently, this reaction was applied to the reactions involving α -iodoketones (Scheme 58).¹⁷⁰

Scheme 56 Tandem radical addition-aldol reaction-lactonization process.

Scheme 58 Triethylborane-mediated carboazidation with α -iodoketones.

Scheme 59 Addition of xanthates to vinyl epoxides.

5.2 Via Xanthate Transfer

The radical addition of xanthates to vinyl epoxides has been described by Zard and has proved to be an efficient method for quaternary carbon formation (Scheme 59).¹⁷¹

5.3 Via Hydrogen Atom Transfer

Ethers and acetals undergo direct intermolecular addition to aldehydes under treatment with Et_3B –air (Scheme 60).¹⁷² A plausible mechanism is depicted in Scheme 60 and involves addition of the 2-tetrahydrofuryl radical to the aldehyde followed by a rapid reaction of the alkoxy radical with Et_3B . Triethylborane has a crucial role because

Scheme 60 Radical hydroxyalkylation of C–H bonds adjacent to oxygen.

Scheme 61 One-step synthesis of mepivacaine.

by reacting with the alkoxy radical, it favors the formation of the condensation product relative to the β -fragmentation process (back reaction). Similar reactions with tertiary amines, amides, and urea are also reported¹⁷³ and applied for the synthesis of ($\pm$)-aphanorphone.¹⁷⁴

Yoshimitsu and Tanaka reported a novel carbamoylation of tertiary amides involving isocyanate radical traps.¹⁷⁵ This reaction was applied for a short synthesis of the local anesthetic mepivacaine (Scheme 61).

The regioselective hydroxysulfenylation of α,β -unsaturated imines was developed by Naito (Scheme 62).¹⁷⁶ It is not clear if the reaction involves the formation of a boron azaenolate (= *N*-borylenamine) or the direct reaction of the radical adduct with oxygen.

An interesting method for the production of methanol from methane was recently developed.¹⁷⁷ In this process, boron trichloride acts as a chain transfer reagent. The key steps of this process are shown in Scheme 63.

Scheme 62 Stereoselective hydroxysulfenylation.

Scheme 63 Conversion of methane to methanol mediated by boron trichloride.

6 BORON DERIVATIVES IN REDUCTIVE PROCESSES

6.1 Complexes of Boranes with Tertiary Amines

The B–H bond dissociation energies (BDEs) of boranes are strongly influenced by complexation with Lewis bases (see **Radical Stability—Thermochemical Aspects**).¹⁷⁸ This offers an opportunity for the development of a new class of reagents that are able to transfer hydrogen to radical intermediates. Roberts investigated the use of amine–borane complexes as hydridic polarity-reversal catalysis.¹⁷⁹ A slow hydrogen atom abstraction step caused by a mismatched polarity can be replaced by two rapid steps with matched polarity. For example, the slow abstraction of an hydrogen atom from acetonitrile by a *tert*-butoxyl radical (mismatched polarity) is replaced by a rapid reduction of the electrophilic *tert*-butoxyl radical with an amine–borane complex (matched polarity) and by the abstraction of an hydrogen atom from acetonitrile by the nucleophilic amine–boryl radical (matched polarity).^{180,181} Application of this concept to the kinetic resolution of chiral

Scheme 64 Kinetic resolution of a γ -lactone.

esters and lactones by using chiral amine–borane complexes lead to interesting enantioselectivities (Scheme 64).^{182–184} More recently, Lalevée showed that *N*-heteroarylboranes exhibit low B–H BDE's and could become useful reagents for the reduction of radicals.¹⁸⁵

6.2 Complexes of Borane with *N*-Heterocyclic Carbenes (NHC boranes)

The use of NHC boranes as hydrogen atom donor was recently investigated.^{186,187} Remarkably, complexation by NHC leads to a very effective decrease of B–H BDEs making these complexes suitable for the reduction of carbon-centered radicals.¹⁸⁸ Barton–McCombie deoxygenation of various xanthates is initiated by AIBN and provides the reduced products in moderate to good yield.¹⁸⁶ The rate constant for the reduction ranges from 1 to $8 \times 10^4 \text{ M}^{-1} \text{ s}^{-1}$.¹⁸⁹ Interestingly, the best results so far have been obtained with NHCs possessing low

Scheme 65 Reduction of a xanthate with a low molecular weight NHC borane.

molecular weights (Scheme 65).¹⁹⁰ The reactivity of the intermediate NHC boryl radical has been investigated and based on these results further optimization and generalization of this system is expected.^{188,191}

6.3 Borohydride

Ryu recently provided experimental indications that tetrabutylammoniumborohydride may also act as a source of hydrogen atom in the hydroxymethylation of alkyl iodides (Scheme 66).¹⁹² Sodium cyanoborohydride is also used to run conjugate addition to acrylates (Giese reaction). In this case, a mechanism implicating an iodine atom-transfer process followed by hydride reduction of the carbon–iodine bond is operative.¹⁹³

Scheme 66 Hydroxymethylation of alkyl iodides.

6.4 Complexes with Water and Alcohols

Wood reported an innovative development of the Barton–McCombie deoxygenation of alcohols allowing to work under tin-free conditions.¹⁹⁴ Trialkylborane–water complexes prove to be efficient reagents for the reduction of xanthates^{194–196} and iodides (Scheme 67).¹⁹⁷ The typically high barriers for hydrogen abstraction from water are lowered dramatically on complexation with BMe₃. The barrier lowering is found to be a consequence of the unique properties of trialkylboranes, acting as Lewis acids toward the closed-shell solvent, but as electron donors toward the evolving oxygen-centered radicals.¹⁹⁸ The rate constant for the hydrogen atom transfer has been measured by Newcomb and a relatively low value of $3 \times 10^4 \text{ M}^{-1} \text{ s}^{-1}$ at 20 °C has been found.^{199,200}

6.5 The Borane–Catechol System

A similar observation was made by Pozzi *et al.* who reported a mild and efficient radical-mediated reduction of *B*-alkylcatecholboranes in the presence

Scheme 67 Barton–McCombie deoxygenation with Me₃B–water complex.

Scheme 68 The reduction of *B*-alkylcatecholboranes by methanol.

of methanol and a radical initiator.²⁰¹ The radical nature of the process was demonstrated by using (+)-2-carene as a radical probe and an *in situ* generated *B*-methoxycatecholborane–methanol complex was suggested as a reducing agent (Scheme 68). Recently, this mechanism was revised based on ¹H- and ¹¹B-NMR studies.²⁰² A mechanism involving catechol as a reducing agent is proposed. Catechol, a chain breaking antioxidant, becomes a source of hydrogen atom in a highly efficient radical chain process.

On the basis of these results, a mild radical procedure for the transformation of organoboranes to alkanes was developed.²⁰³ 4-*tert*-Butylcatechol (TBC), a well-established radical inhibitor and antioxidant, is acting as a source of hydrogen atom. An efficient chain reaction is observed owing

Scheme 69 Reduction of organoborane with 4-*tert*-butylcatechol.

to the exceptional reactivity of phenoxyl radicals toward alkylboranes. The reaction has been applied to a wide range of organoboron derivatives such as *B*-alkylcatecholboranes, trialkylboranes, pinacolboronates, and alkylboronic acids (Scheme 69). Furthermore, the so far elusive rate constants for the hydrogen transfer between secondary alkyl radical and catechol derivatives have been experimentally determined ($\text{TBC} : \text{KH} = 1.3 \times 10^6 \text{ M}^{-1} \text{ s}^{-1}$). Interestingly, they are less than one order of magnitude slower than tin hydride at 80 °C making the catechols particularly attractive reagents for a wide range of transformations involving C–C bond formations.

7 BORON-CONTAINING RADICALS AND RADICAL TRAPS

7.1 Allylboron Derivatives

The addition of α -iodoesters to several allylboron derivatives was investigated by Oshima.⁸¹ Diallylmethoxyborane affords the allylation product in good yield but the reaction is limited to iodide radical precursors (Scheme 70). No reaction is observed with the corresponding bromide suggesting that the mechanism involves an iodine atom-transfer process followed by ionic elimination of the iodoboron derivatives. A conjugate addition–allylation process is reported.

The addition of an ester α -xanthate to allylpinacolborane affords the simple addition product resulting from a xanthate transfer in good yields (Scheme 71).^{76,204}

7.2 Alkenylboron Derivatives

The use of alkenylboranes as radical trap has been pioneered by Matteson *et al.*²⁰⁵ and Carboni.²⁰⁶ Interestingly, nucleophilic radicals generated from iodides (Scheme 72) and Barton esters add

Scheme 70 Radical allylation with diallylmethoxyborane.

Scheme 71 Xanthate-transfer addition to allylpinacolborane.

Scheme 72 Giese-type addition to vinylpinacolborane.

efficiently to vinylpinacolborane. Zard reported the addition of alkyl²⁰⁴ and acyl radicals via xanthate transfer to vinylpinacolborane.²⁰⁷ This last reaction proved to be an efficient procedure for the preparation of β -borylatedenones.

Cyclization reactions involving alkenylboranes represent an efficient approach for the preparation of alcohols.^{206,208,209} Lee reported an interesting

approach to cyclic diols from easily available starting materials (Scheme 73).²⁰⁸

Batey developed boron-tethered radical cyclizations and observed an unexpected 1,2-shift (Scheme 74).¹⁰ The mechanism of this rearrangement is not clear but a homolytic substitution at boron via a three-membered ring transition state was proposed.

Scheme 73 Preparation of cyclic diols via radical cyclization.

Scheme 74 Boron-tethered radical cyclization: an unexpected 1,2-shift.

7.3 Diboron Radical Traps

A Sandmeyer-type reaction involving bis(pinacolato)diboron has been recently reported (Scheme 75).²¹⁰ This metal-free process involves most probably aryl radicals that are trapped by the diboron species. This mechanism is supported by the observation that phenylpinacolborane is generated when dibenzoyl peroxide is heated in the presence of the bis(pinacolato)diboron.

7.4 Alkylborane Radical Traps

The radical addition of alkylboranes to α,β -unsaturated ketone and aldehyde produces transient boron enolates that are usually hydrolyzed (see Section 4.1.1). Interestingly, these boron enolates have been used in aldol reactions as shown previously (Scheme 25). The generation of boron enolates from α -iodocarbonyl compounds represents an interesting alternative to the use of bases.¹⁰² This approach is illustrated by the work of Danishefsky who has treated an α -iodolactam in the presence of the aldehyde with triethylborane at -78°C to effect a rapid, quantitative, and completely stereoselective aldol coupling (Scheme 76). This reaction provides the full skeleton of the naturally occurring alkaloid UCS1025A.²¹¹ This remarkable process, which presumably passes through the intermediacy of a boron enolate,

produces no β -elimination product and excess aldehyde may be recovered intact.

7.5 α -Boryl Radicals

The cyclization of radicals substituted by a boron atom was reported by Carboni.²⁰⁶ More recently, Batey reported inter-²¹² and intramolecular²¹³ reactions involving α -boryl radicals. The radicals are easily generated from the corresponding iodides and possess an ambiphilic character.

8 CONCLUSIONS

The tremendous development of the use of radicals in organic synthesis and the necessity to avoid the use of tin derivatives because of their toxicity has led to a revival of the radical chemistry of organoboranes. The use of triethylborane as an initiator for radical chain reactions is now part of the classical arsenal of organic chemists. Generation of more complex and functionalized radicals from organoboranes is of great interest since a large variety of olefins become a potential source of radicals. Interestingly, organoboranes could also play the role of chain transfer reagents in radical processes. Owing to the particularly rich reactivity of boron derivatives, the design of tandem processes involving radical and nonradical

Scheme 75 Sandmeyer borylation.

Scheme 76 Key aldol process in the synthesis of UCS1025A.

reactions is possible. Boron derivatives are also at the origin of some of the most promising reagents to replace tin hydride in radical-reductive processes. Spectacular developments in this particular field are expected in a near future.

ACKNOWLEDGMENTS

Support from the Swiss National Science Foundation for our research on boron-based radical chemistry is gratefully acknowledged. The University of Melbourne and particularly Professor Carl Schiesser are warmly thanked for their hospitality during the preparation of this manuscript.

Unusual Cyclizations

Kerry Gilmore and Igor V. Alabugin

Department of Chemistry and Biochemistry, Florida State University, Tallahassee, FL, USA

1 INTRODUCTION

The ability to create cyclic structures from acyclic precursors in a regio- and stereocontrolled manner is indispensable for the construction of complex organic molecules. Radical cyclizations, in particular those which form five- and six-membered cycles, are well documented and reliable elements of modern synthetic designs. However, some cyclization patterns remain underrepresented. In this article, we analyze several factors that render such cyclizations unusual.

The first factor, which is well recognized and discussed in detail in two earlier reviews by Srikrishna¹ and Walton,² is the ring size. The formation of smaller three- and four-membered rings is disfavored by the strain effects in the products, whereas the formation of medium-size 7+-membered rings is disfavored by entropic factors. Owing to the presence of two excellent reviews on these particular types of underrepresented radical cyclizations, this discussion mostly concentrates on the new, post-2006, developments in this area.

The second factor that makes certain cyclizations unusual is stereoelectronics. A ring closure proceeds rapidly only when efficient overlap of the bond-forming orbitals is possible. Guidelines based on the favorability of these interactions, allowing for the rational design of cyclization reactions, are based on “the Baldwin rules”³ and, for the radical processes, on a set of fundamental principles offered by Beckwith.^{4,5} It is well recognized that stereoelectronic factors favor exocyclizations in tetragonal

and trigonal systems, while for digonal closure, the principles of Baldwin and Beckwith diverge (*vide infra*). The (3,4,5,6)-*endo*-tet and (3,4,5)-*endo*-trig processes are unfavorable according to *both* Baldwin and Beckwith rules. Although the *endo*-tet reactions proceed through a cyclic transition state, they do not lead to cyclic products and, thus, are not included in this article (Figure 1).

Thermodynamics is the third factor that can influence how common a cyclization pattern is. Although endothermic ring closures are less common in the literature, such closures can be rendered efficient when they are coupled to a subsequent thermodynamically favorable step. Recent literature includes a number of such cyclizations that occur efficiently when the higher energy intermediate is trapped by a fragmentation or a fast exothermic cyclization.

Finally, the choice of functional group and the type of bond formed at the point of ring closure remains relatively limited. Attack at a double bond is the most common choice for a cycle-forming process. Attack at the single or triple bond (-tet or -dig cyclizations, respectively) remains relatively underrepresented. Similarly, the formation of a C–C bonds are the most prominent in radical cyclizations. The two ways in which C–heteroatom bond is formed include either addition of a heteroatom radical to an olefin/alkyne or addition of a carbon radical to the heteroatom of a C=X bond. Both of these unusual forms of cyclic closure are discussed with respect to both nitrogen and oxygen species.

Taking into account these considerations, this article is organized as follows. We begin with a

Figure 1 Comparison of the six possible patterns for intramolecular radical reactions. All but the *endo*-tet paths lead to cyclic products.

short discussion of the recent developments in the formation of small cycles (Section 2). We continue with stereoelectronically unfavorable modes of cyclic closure in the formation of five-membered rings (the 5-*endo* cyclizations). In the latter case, we pay special attention to such processes that involve alkynes (the 5-*endo*-dig cyclization). These processes are particularly unusual as the first example of an efficient 5-*endo*-dig radical cyclization at ambient conditions was reported only in 2002⁶ and an efficient C–C bond formation via a 5-*endo*-dig radical closure was first achieved only in 2008 (Section 3).⁷ We then discuss an unusual type of cyclization reaction where *two* radical centers are formed *simultaneously* from a closed-shell reactant in the construction of five- and six-membered rings (Section 4). In Section 5, we briefly summarize the post-2006 developments in the formation of larger cycles not covered in the recent review of Walton.² In Section 6, we discuss radical cyclizations that involve the formation of carbon–heteroatom bonds.

A selection of unusual cyclizations discussed in this work along with the relevant kinetic information are presented in Figure 2.

2 UNUSUAL CYCLIZATIONS LEADING TO THE FORMATION OF SMALL CYCLES

The formation of small cycles is difficult owing to the intrinsic strain energy accumulated in the small rings. As a result, thermodynamic factors usually favor the reverse reaction—the radical ring-opening. For example, both 3-*exo* and 4-*exo* cyclization modes are stereoelectronically favorable because the orbital overlap needed to form the bond closing the cycle is easily achieved. However, owing to the microscopic reversibility principle, the same stereoelectronic factors make the cyclopropylmethyl or cyclobutylmethyl ring-opening favored as well. In fact, the cyclopropylmethyl radical opening is so fast and reliable that it serves as a “radical clock” to determine the rate of other radical reactions (see **Radical Kinetics and Clocks**).^{22,23} The kinetics of this ring-opening has been studied extensively.^{24,25} Strategies for shifting these equilibria are based on increasing the thermodynamically favorability of cyclic product formation. Several approaches have been used to overcome the unfavorable strain effect of these small rings (19.2 kcal mol^{−1} in cyclopropane, 21.0 kcal mol^{−1} in cyclobutane)^{26,27}: (i) conjugative stabilization of the radical center, (ii) destabilization of acyclic reactants with strain, (iii) coupling cyclization steps with exothermic and irreversible fragmentation steps.

2.1 Three-Membered Rings

Although the rate constant for ring-opening in the parent cyclopropylmethyl radical is approximately 3 orders of magnitude greater than that of 3-*exo*-trig cyclization at 27 °C (9×10^7 vs 2×10^4 s^{−1}), this equilibrium can be shifted by the use of radical-stabilizing groups on the olefin. In 1990, Ingold *et al.* reported a rate constant for 3-*exo*-trig cyclization of 1,1-dideutero-4-phenyl-3-butenyl radical to be 1.2×10^7 s^{−1} at 42 °C, where the ring-closed form had become thermodynamically preferred.⁹ Beckwith and Bowry found that ester substitution also favorably shifted the equilibrium

Figure 2 Rate constants (k_c , s^{-1}) of unusual cyclizations discussed in this work forming carbocycles (a) and heterocycles (b) (**1** Ref. 8, **2** Ref. 9, **3** Ref. 10, **4** Ref. 11, **5** Ref. 11, **6** Ref. 12, **7** Ref. 13, **8** Ref. 14, **9** Ref. 15, **10** Ref. 15, **11** Ref. 16, **12** Ref. 17, **13** Ref. 18, **14** Ref. 19, **15** Ref. 20, **16** Ref. 20, **17** Ref. 19, **18** Ref. 20, **19** Ref. 21, **20** Ref. 21).

toward cyclic products (Ph k_c/k_{ro} = 17.5, CO₂^tBu k_c/k_{ro} = 1.3).^{23,28}

The relative magnitude of strain and conjugation effects on the thermodynamically controlled efficiency of 3-*exo*-trig cyclization is illustrated by comparison of data by Kuvila and coworkers on the cyclizations of bicyclic[2.2.1] and [2.2.2] halides. Reaction of the more strained [2.2.1] system resulted in a 1 : 1 mixture of cyclopropane and reduced products without the need for radical-stabilizing groups. When the strain of the reactant was decreased, no cyclopropyl products were observed. However, upon introduction of radical-stabilizing aromatic or ethynyl groups, the 3-*exo*-trig product could be trapped efficiently in 65–95% yields (Scheme 1).²⁹

Allylic stabilization can also tip the balance in favor of the ring-closed product. Journet and Malacria,³⁰ as well as Weng and Luh,³¹ have

observed a regioselective 3-*exo*-trig closure to terminate cascades, forming an allylicly stabilized cyclopropylmethyl radical (Scheme 2). Although a 6-*endo*-trig closure would also give an allylic radical, no product derived from this path was observed.

Čeković and Saičić have shown that cyclopropylcarbinyl radicals can also be trapped through an exothermic β -scission.^{32,33} Introduction of an allylic phenylthio group in the fifth position (with respect to the site of initial radical formation) was sufficient to obtain vinyl cyclopropanes in 43–60% yields (Scheme 3). Recently, this strategy has been adopted by Fensterbank, Malacria, and coworkers, who utilized the elimination of a chlorine atom to terminate a radical cascade of cyclizations, using the (dichloromethyl)dimethylsilyl ether functionality as both a site for initiation (loss of the first chlorine

Scheme 1 3-*Exo*-trig cyclizations facilitated by strain in the starting material and conjugative stabilization of the cyclopropylcarbinyl radical.

Scheme 2 3-*Exo*-trig closures forming stabilized allylic radicals.

Scheme 4 3-Exo-trig closure onto an aromatic ring as a key step in a phenol-benzoate conversion via *O*-neophyl rearrangement/fragmentation cascade.

atom) and termination (loss of the second chlorine atom).³⁴ The stability of the intermediate radical was found to be critical to the success of the full cascade. While primary radicals underwent 3-*exo*-trig closure efficiently (77%), the tertiary radical did not afford the desired tricyclic product (Scheme 3).³⁴

Baroudi and Alabugin have shown that the competition between scission of a $\text{O}-\text{C}_\beta$ bond^{35–39} and 3-*exo*-trig cyclization on aromatic rings (*O*-neophyl rearrangement) is shifted in favor of cyclization when C_β is sp^2 -hybridized.^{40–47} For these systems, the 3-*exo*-trig product does not always correspond to an energy minimum and, even if formed, reversibly

opens to establish a transient equilibrium between the *O*- and *C*-centered radicals, usually favoring the more stable *C*-centered radical.^{48–56} The direction of this reaction was controlled via incorporation of a delayed fragmentation step, cleaving the weak $\text{C}-\text{S}$ bond (Scheme 4). This procedure can be used for metal-free transformation of phenols into benzoates and benzamides.

Jones and coauthors reported a 3-*exo*-trig cyclization on an allylic radical⁵⁷ in the process of photochemical isomerization of 1-benzoyloxy-9,10-anthraquinones (Scheme 5). In contrast to other *O*-neophyl radical rearrangements

Scheme 5 The photochemical isomerization of 1-benzyloxy-9,10-anthraquinones, where the 3-*exo*-trig closure is coupled with radical recombination.

Scheme 6 3-*Exo*-tet radical cyclizations.

(see **Radical Rearrangements: Ester-Substituted Radicals and Hydrogen Atom Migrations**), the energy cost for the formation of a strained, dearomatized three-membered intermediate is in this case partially compensated by the coupling of the two radicals and return to the ground state hypersurface.

In contrast to the 3-*exo*-trig cyclization, their 3-*exo*-tet counterparts (intramolecular S_H2 reaction) are essentially irreversible. Curran and Gabarda found that the reductive radical cyclizations of simple 1,3-diiodopropane derivatives are efficient (86%) with less than 5% of doubly reduced product observed (Scheme 6). The rate for cyclic closure was determined to be $\sim 5 \times 10^5 \text{ s}^{-1}$.⁸ Togo and coworkers have shown that 1,3-dibromopropanes also undergo efficient 3-*exo*-tet closure in the presence of SmI_2 or In powder. The possible ionic mechanism, via reduction of the carbon radical prior to cyclization, was ruled out when only cyclopropyl products were obtained upon reaction in aqueous media and no products of protonation of the putative anion was observed.^{58,59} Peroxide bonds have also

been shown to be good platforms for 3-*exo*-tet closure (*vide infra*).

2.2 Four-Membered Rings

As discussed above, exocyclic closure is stereo-electronically favored. However, even under kinetic control, thermodynamic contributions can modify selectivity and relax intrinsic stereoelectronic preferences in two ways. First, in accordance with the Hammond–Leffler postulate,^{60,61} exothermic reactions have early, reactant-like transition states and consequently require less distortion from the reactant geometry in order to reach the transition state (TS).⁶² Decreased distortions often alleviate geometric requirements needed to reach the optimal bond-forming trajectories. Second, thermodynamic contributions directly lower the activation barriers in exothermic reactions relative to the barriers of the analogous thermoneutral or endothermic processes. Unlike other ring closures (3-*exo*/4-*endo*,

5-*exo*/6-*endo*) where both products have a similar amount of strain, the competition between 4-*exo* and 5-*endo* closure onto both olefins and alkynes is delicately balanced because the aforementioned thermodynamic contributions favor the formation of 5-*endo*-products. In this section, we discuss several examples where the interplay of sterics and electronics can be adjusted to efficiently afford the cyclobutyl product.

Similar to the 3-*exo*-trig closures discussed above, 4-*exo*-trig reactions are reversible and, in the absence of sufficient stabilizing groups, the isomerization equilibrium is shifted to the acyclic radical. For example, while 2-bromo-3,3-dimethylpentene gives only reduction product under standard tin radical conditions,⁶³ a cyano group provides enough stabilization to the cyclobutylcarbiny radical to yield an approximately 1 : 1 mixture of cyclic and reduced products.¹² The combined effects of methylthio and *p*-tolylsulfonyl groups provide slightly higher cyclic : reduced product ratios,⁶⁴ whereas ester substitution was sufficient to exclusively obtain the 4-*exo*-trig product in 72% (Scheme 7).⁶⁵

The majority of 4-*exo* radical cyclizations in the literature are focused on the synthesis of β -lactams from carbamoylmethyl radicals, a process that was thoroughly covered by the recent review of Walton.² The factors that influence the regioselectivity of cyclic closure of these systems have been reviewed by Ishibashi.⁶⁶ The results indicate that 4-*exo*-trig closure of carbamoylmethyl radicals proceeds under kinetic control⁶⁶ as the authors observed the 4-*exo*-

to 5-*endo*- switch in regioselectivity when the temperature was increased from room temperature to 110 °C.^{67,68}

Control over the delicate balance in this pair of reactions can be challenging. While conjugation with an olefin provided sufficient stabilization to afford cyclopropanes (*vide supra*), Majumdar and coworkers found that it was not enough to prevent a 5-*endo*-trig closure where an anomeric radical was formed.⁶⁹ However, when the cyclobutylcarbiny radical was conjugated to an indole ring, the initial ring closure was selective for the 4-*exo*-trig pathway (Scheme 8).⁷⁰

As shown by Clark *et al.*, the regioselectivity can also be controlled through steric effects at the site of attack (Scheme 9). When the enamine was *exo* to the cyclohexane ring, the carbamoylmethyl radical (generated using a resin-bound CuBr catalyst) selectively attacked the less-hindered position in a 4-*exo*-trig fashion, yielding the β -lactam. When an *N*-cyclohexenyl group was employed, attack again occurred at the least hindered position, this time producing a mixture of 5-*endo*-trig products.⁷¹

Another way to facilitate 4-*exo*-trig closure is through the restriction of conformational flexibility and trapping of the cyclobutylmethyl radical in a subsequent cyclization. After an initial 5-*exo*-trig cyclization, Gharpure and Porwal found that the product of 4-*exo* closure onto the internal olefin could be successfully trapped in a final 5-*exo*-trig closure (Scheme 10).⁷² However, attack at an exocyclic vinyl ether in the absence of an intramolecular

Scheme 7 Both the Thorpe–Ingold effect and stabilization of the cyclic radical are necessary to promote 4-*exo*-trig closure of primary carbon radicals.

Scheme 8 Effect of cyclic radical stability on 4-*exo*-trig/5-*endo*-trig regioselectivity.

Scheme 9 Effect of alkene substitution on the 4-*exo*-trig/5-*endo*-trig regioselectivity.

Scheme 11 Control of efficiency and regioselectivity by substituents on both the olefin and nitrogen.

radical trap, produced no cyclobutyl product.⁷³ This is in contrast to Jung's results (Scheme 7) where a carbon radical adjacent to two alkoxy groups underwent 4-*exo*-trig closure onto an α, β -unsaturated ester in 72% yield.⁶⁵

As mentioned previously, the synthesis of β -lactams has been a major focus of the 4-*exo*-trig literature. As discussed by Walton, the less common retrosynthetic disconnection in their formation involves a carbamoyl radical.² A recent example detailed the substituent effects on both the olefin and the nitrogen. For the *N*-benzyl derivatives, high regioselectivity was only observed for substituted olefins. However, the acyclic reduced product was a significant by-product, even when R^2 was a phenyl group. When the benzyl group was replaced with an electron-withdrawing Boc group, the carbamoyl radical closed efficiently onto a terminal olefin in a 4-*exo*-trig fashion without the formation of products derived from 5-*endo*-trig closure or reduction of the carbamoyl radical (Scheme 11).⁷⁴

The facilitating effect of the N-substituent on the 4-*exo*-trig process has been examined by Walton *et al.* for carbamoyl radical closure onto oximes. The rate of these cyclizations is comparable to the analogous closures onto a 2-cyclohexenyl group ($k_{\text{C}=\text{C}} = 5 \times 10^4 \text{ s}^{-1}$, $k_{\text{C}=\text{NOR}} = 3 \times 10^4 \text{ s}^{-1}$ at 300 K).¹⁵ The authors performed DFT calculations (B3LYP/6-31+G** level) and found that the activation barrier for 4-*exo* closure dropped from 9.2 to 4.8 kcal mol⁻¹ in parallel with an increase in the exothermicity of cyclic closure (−2.5 to −9.8 kcal mol⁻¹) when the size of the N-substituent was increased from H to *t*-Bu (Scheme 12).

Although 4-*exo*-trig cyclizations are well documented, the literature examples of regioselective 4-*exo*-dig radical closures are scarce. A single

Scheme 12 Comparison of the rates of 4-*exo*-trig closure of carbamoyl radicals onto olefins and oximes. Activation barriers and exothermicities of 4-*exo*-trig closure onto an oxime, varying the nitrogen substituent (kcal mol⁻¹, B3LYP/6-31+G** level).

example of 4-*exo*-dig closure of an alkyl radical has been observed experimentally (Scheme 13). This transformation has been reported by Malacria *et al.* as part of radical cascade leading to the formation of bicyclo[3.1.1]heptanes.^{75,76} The overall yield for the product is 85% yield after reaction with MeLi, which can serve as a lower boundary estimate for the 4-*exo*-dig step. The surprising efficiency of this unprecedented transformation has been attributed to fast intramolecular trapping of the exocyclic vinyl radical via 1,6-*H* transfer (Scheme 13) from a SiCH₃ moiety.

Scheme 13 4-Exo-dig cyclization of an sp^3 carbon with a fully saturated linker as part of a cascade. Bonds formed in the initial 5-*exo*-dig/1,6-*H* transfer/6-*endo*-trig cascade steps occurring before the 4-*exo*-dig closure are shown in red.

Scheme 14 (a) Regioselective 4-*Exo*-dig cyclization of *N*-acyl radicals onto terminal and phenyl-substituted alkynes. (b) Relative energies (in kcal mol⁻¹) of the radical intermediates calculated at UB3LYP/6-311G(d,p) and UB3PW91/cc-pVTZ (in parentheses) levels. [Reproduced from Ref. 77. © Elsevier, 2009.]

Fujiwara *et al.* have reported that the cyclizations of carbamoyl radicals, generated via photolysis of carbamotelluroates, proceed with high 4-*exo*-selectivity for terminal- and phenyl-substituted alkynes in up to 83% yield.⁷⁷ Only when R^2 was an ethyl group did 5-*endo*-dig closure becomes competitive (4-*exo*:5-*endo* ratio = 2.5:1). In accordance with the experimental findings, DFT calculations found that the 4-*exo* pathway is strongly preferred kinetically over the 5-*endo* process for $R^2 = \text{Ph}$ but by a much smaller margin (0.8 kcal mol⁻¹) when $R^2 = \text{Me}$

(Scheme 14). This important work suggests that efforts into these unusual radical cyclizations (4-*exo*-dig) should be continued.

The above experimental results fully agree with the first comprehensive computational analysis of 4-*exo*-dig radical cyclizations by Alabugin and Manoharan.⁷⁸ The calculated 4-*exo*-dig barriers were predicted to be slightly lower than the barrier for competing 5-*endo*-dig cyclization for several parent radicals. These results regarding the competition between 4-*exo*/5-*endo* closure are discussed in detail in the subsequent section (Figure 4).

3 FIVE-MEMBERED RING FORMATION DISFAVORED BY STEREOELECTRONIC FACTORS

Although strain is no longer an issue in the formation of five-membered rings, there are other factors that can make their formation unusual. While exocyclizations are favorable stereoelectronically, the orbital overlap necessary to form the bond closing the cycle is not easily achieved for endocyclic closures of less than six atoms. However, owing to the generally greater thermodynamic stability of five-membered rings, 5-endo cyclizations can often compete successfully with 4-exo closures. We outline the stereoelectronic factors that influence this delicate equilibrium and those that can be efficiently tuned to afford the endocyclic product.

3.1 5-Endo-trig

The two popular set of guidelines proposed by Baldwin³ and Beckwith^{4,5} for the design of cyclizations agree that 5-endo-trig cyclizations are unfavorable but disagree regarding the feasibility of 5-endo-dig cyclizations. While Beckwith's guidelines state that all exoclosures are generally favorable, the Baldwin rules suggest that the 5-endo-dig closure should be more favorable than the competing 4-exo-dig cyclizations. These guidelines are based upon stereoelectronic and steric factors pertaining to the transition state structures of the respective ring closures. As such, knowledge regarding the angle of approach of the attacking species is critical.³ The ideal attack trajectory for trigonal systems was defined based on the well-established Bürgi *et al.*⁷⁹ angle of attack on sp^2 carbon atoms ($\sim 105^\circ$ – 109°). This trajectory optimizes the overlap of incoming nucleophiles with the trigonal $\pi_{C=Y}^*$ orbital. As a consequence, 5-endo-trig cyclizations were considered unfavorable owing to the strained transition state in achieving this approach angle. However, there are a plethora of examples of the respective trigonal closure. Several excellent reviews thoroughly cover the wide variety of literature on this topic through 2002.^{80,81}

Chatgililoglu, Guerra *et al.* examined the competition between 4-exo-trig and 5-endo-trig closures of carbamoyl radicals via competitive kinetic studies as well as a detailed theoretical study (UB3LYP/6-31G* level).¹⁶ They found that,

contrary to previous beliefs, 5-endo-trig closure is kinetically favored, exhibiting lower activation barriers than 4-exo-trig in almost every case. Although the angle of attack for 4-exo closure (111° – 118°) is closer to the angle of intermolecular addition of a methyl radical to ethylene⁸² compared to that of 5-endo (87° – 89°), there is a significant amount of strain energy in attaining the transition state for exocyclic closure ($6.1 \text{ kcal mol}^{-1}$ vs $0.8 \text{ kcal mol}^{-1}$ for 5-endo). However, these data should not be taken as an evidence of intrinsic stereoelectronic preference for the endo-attack, because the 5-endo-trig cyclizations are much more exothermic than the 4-exo-trig alternative. When the thermodynamic contribution is removed using Marcus theory,⁸³ the intrinsic barriers reveal the inherent preference for 4-exo-trig closure of both the parent and carbamoyl radicals (Figure 3). (K. Gilmore and I. V. Alabugin, unpublished work.)

The 5-endo-trig regioselective closure of carbamoylmethyl radicals has been exploited for the formation of saturated bicyclic γ -lactams.⁶⁸ The yield of the 5-endo-trig product can be improved by stabilizing the acyclic radical, for example, the primary versus benzylic example in Scheme 15.⁸⁴ Ikeda and coworkers⁸⁵ have improved the efficiency of γ -lactam formation of a primary carbamoylmethyl radical via polarization of the olefin.⁸⁴ This 5-endo-trig/radical conjugate addition (RCA) strategy was later utilized by El Bailly in the synthesis of (–)- γ -lycorane alkaloid.⁸⁶

5-endo-trig RCAs^{87,88} have also been used within domino transformations. In particular, Ishibashi and coworkers have reported a number of unusual cascades. An aryl radical was generated with the intention of trapping via regioselective 6-endo-trig closure onto an enamine followed by 5-endo-trig closure onto the pendent α,β -unsaturated carbonyl.⁸⁹ The parent system, however, gave only an 11% yield of the 6-endo closure with no trace of the cascade product. Introduction of a methyl group α to the carbonyl, to stabilize the 5-endocyclic radical, afforded 26% of the bicyclic product and an equal amount of the bicyclic reduced product (no 5-endo, Scheme 16).⁹⁰ As seen with Ikeda's work above (Scheme 15),⁸⁴ stabilization of the pre-5-endo radical also increases the overall reaction yield. In this example, a tertiary intermediate radical was trapped to yield the tricyclic product in 22–36% yield, without the need for added stabilization at the olefin.⁸⁹ Ishibashi *et al.* have published

Figure 3 Calculated (UB3LYP/6-31G* level) exothermicities and activation barriers (in kcal mol⁻¹) for the parent and carbamoylmethyl radical depicting the kinetic and thermodynamic favorability of 5-*endo*-trig closure.¹⁶ Intrinsic barriers reveal the inherent preference for exocyclic closure (ovals).

Scheme 15 γ -Lactam formation by 5-*endo*-trig closure of carbamoylmethyl radicals.

even more unusual examples where a 5-*endo*-trig cyclization is preceded by a 7-*endo*-trig closure onto a cyclic enamine (Scheme 16). The tertiary radical underwent 5-*endo*-trig onto the α, β -unsaturated system in 27–55% yield. This cascade gave slightly higher yields than the respective 6-*endo*/5-*endo* sequence. The authors have successfully utilized this method for the rapid construction of several natural products.^{91–94}

Cascades terminating with a 5-*endo*-trig closure can also be mediated by 1,5-*H* atom transfer (Scheme 17). For example, intramolecular hydrogen abstraction by an aryl radical resulted

in the anomerically stabilized benzylic radical, which Kamimura and coworkers successfully trapped via RCA in 56% yield.⁹⁵ A 1,5-hydrogen abstraction has been used as a key step for setting up a 5-*endo*-trig closure by Malacria and coworkers in their continuing studies on radical reactions of bromomethyltrimethylsilyl propargyl ethers.⁹⁶ Fensterbank, Malacria, *et al.* expanded this work and found that the presence of a sterically demanding quaternary propargylic position was critical to the success of the 5-*endo*-trig closure, which proceeded in up to 74% yield.⁹⁷

Scheme 16 Radical cascades that are terminated by 5-endo-trig RCA. Bonds formed prior to the 5-endo closure are shown in red.

Scheme 17 5-Endo-trig closure set up by 1,5-*H* atom transfer.

Recently, several other complex cascades have also been terminated in efficient 5-endo-trig cyclizations succeeding 1,5-translocation. In particular, Nanni, Zanardi *et al.* have shown that the addition of a cyclohexyl radical to an aryl isothiocarbamate initiates sequential 5-*exo*-dig closure and 1,5-*H* atom transfer, generating a tertiary anomeric radical (Scheme 18). This radical regioselectively closed in a 5-endo-trig fashion to give a highly

delocalized radical and the spirocyclic product ultimately in 40% yield.⁹⁸

Alabugin and coworkers have set up an efficient 5-endo-trig cyclization via a radical transformation of aryl triynes capped with trimethylsilyl (TMS) groups. This cascade involved chemoselective addition of the Bu_3Sn radical to the central triple bond, two radical cyclizations (5-*exo*-dig and 6-*exo*-dig), and abstraction of a hydrogen atom from the TMS

Scheme 18 5-Endo-trig closure of a tertiary carbon radical, set up by an addition, 5-*exo*-dig, and 1,5-*H* atom-transfer cascade.

Scheme 19 5-Endo cyclization of a silylmethyl radical forming a highly delocalized radical. Bonds formed prior to the final closure are shown in red.

Scheme 20 Regioselective closure of an aryl radical yielding the 5-endo radical product stabilized both anomerically and conjugatively.

Scheme 21 5-Endo-dig radical cyclization of Si-centered radical.

group (Scheme 19). While this abstraction was found to be mildly endothermic and had a significant activation barrier (5.3, 16.1 kcal mol^{−1}, respectively, at the UB3LYP/6-31G**//UB3LYP/3-21G* level of theory), the 5-endo-trig closure of the resulting primary radical was highly exothermic (−51.5 kcal mol^{−1}) owing to the aromatization of the polycyclic core.⁹⁹

While the above 5-endo-trig cyclizations involve alkyl radicals, Fuwa and Sasaki have shown that aryl radicals efficiently close onto enamines bearing an aromatic group α to the nitrogen. The reaction works equally well using either Bu₃SnH/azobisisobutyronitrile (AIBN) or SmI₂/*t*-BuOH, providing the hydrogenated indoles in 51–85% (Scheme 20).¹⁰⁰

3.2 5-Endo-dig

While the respective trigonal closure is well established, as with the competing 4-exo cyclizations,

5-endo-dig radical cyclizations remained virtually unknown until recently. The 2002 report by Studer remained the only example of an efficient 5-endo-dig cyclization proceeding under kinetic control at relatively mild conditions (Scheme 21).⁶ The efficiency of this 5-endo cyclization is in excellent agreement with the relatively low cyclization barrier of ~ 6 kcal mol^{−1} calculated for this reaction by Alabugin and Manoharan⁷⁸ who have shown that, in addition to the stereoelectronic consequences caused by the presence of long C–Si bonds, this process is assisted by captodative SOMO–LUMO (singly occupied molecular orbital–lowest unoccupied molecular orbital) and HOMO–SOMO (highest occupied molecular orbital–singly occupied molecular orbital) interactions and the β -Si-effect.^{101–103}

An earlier report of the 5-endo-dig closure of O- and S-centered radicals, formed from 2-methoxyphenyl- and 2-methylthiophenyl-substituted phosphorus ylides, proceeded only under drastic

Scheme 22 5-Endo-dig radical cyclizations involved in FVP of substituted phosphorus ylides.

Table 1 Calculated activation barriers, reaction energies, and intrinsic barriers (kcal mol^{-1}) for the 5-endo-dig cyclization of *O*-X-substituted ($X = \text{N}, \text{O}, \text{and CR}_2$) ethynyl benzenes along with the incipient $\text{C} \cdots \text{X}$ distances ($\text{\AA}$) at the UB3LYP/6-31G** level.

	$r(R)$	$r(\text{TS})$	$\Delta E^\ddagger$	ΔE_τ	ΔE_o

conditions (flash vacuum pyrolysis (FVP) at 850°C , Scheme 22).^{104–106}

The activation barriers for these closures were calculated by Alabugin and Manoharan (Table 1).⁷⁸ As evidenced by the experimental conditions, the cyclizations are only expected to proceed under high temperatures. The trends in calculated reaction energies are controlled by the interplay of *gain* of aromatic stabilization and *loss* of conjugative radical stabilization as the starting materials are transformed into the products. The differences in reaction exothermicities are partially translated into the activation barriers. Interestingly, the cyclizations of CN- and NMe_2 -substituted radicals have almost identical reaction energies but the barrier is more than 10 kcal mol^{-1} lower in the case of the donor substituent. The data strongly suggest that both the activation energy ($\Delta E^\ddagger$) and the intrinsic reaction barrier (ΔE_o) decrease dramatically when electron density increases at the radical center.^{107–116}

Alabugin and coworkers investigated the apparent discrepancy between the Baldwin rules and scarcity of efficient radical 5-endo-dig cyclizations in an initial computational⁷⁸ and a subsequent experimental study.⁷ Analysis of the general factors controlling the efficiency of this process using coupled cluster and DFT methods revealed that the barriers for the parent 5-endo-dig and 4-exo-dig cyclizations are essentially identical, despite the

much higher exothermicity for the 5-endo-dig closure (Figure 4). According to these data, both cyclizations are expected to be sufficiently slow ($\Delta E^\ddagger(5\text{-endo}) = \Delta E^\ddagger(4\text{-exo}) = 17.6 \text{ kcal mol}^{-1}$ at UB3LYP/6-31G** level), potentially allowing side reactions to become competitive.

According to the DFT computations, the analogous cyclizations of vinyl radicals should be significantly faster ($\Delta E^\ddagger \sim 13\text{--}15 \text{ kcal mol}^{-1}$). Notably, the position of the double bond in the reactant is predicted to have a noticeable effect on the cyclization energy and selectivity. An interesting prediction (not confirmed yet experimentally) is that when the vinyl moiety is inside the new five-membered ring (the π -endo closure), 5-endo-dig cyclization should be kinetically favored over the 4-exo closure. In contrast, when the vinyl group is outside of the new ring (the π -exo closure), 4-exo-dig cyclization has a $0.8 \text{ kcal mol}^{-1}$ lower barrier despite being less exothermic than the 5-endo-dig process (Figure 4). Cyclizations of stabilized allyl radical are unfavorable because of the significant penalty caused by the 90° rotation of the radical orbital out of conjugation before it can reach the in-plane π -bond of the target alkyne.

The first efficient experimental 5-endo-dig radical closure of a carbon-centered radical, reported by Alabugin *et al.*,⁷ was discovered when radical cyclizations of 1,5-diynes were triggered with tosyl radicals. The 5-endo-dig product was formed

in 51–72% yield upon photolytic generation of Ts radicals from TsBr at the room temperature (Scheme 23). Yields were noticeably lower (2–23%) upon thermal activation (refluxing C₆H₆, AIBN). The cyclizations were also stereoselective, since the sulfonyl moiety is capable of selectively lowering the activation barrier for 5-*endo*-dig closure through a favorable hydrogen-bonding interaction with the relatively acidic sp-hybridized C–H bond (Table 2). A favorable stereoelectronic alignment of the vicinal

diols (the gauche effect¹¹⁷) preorganized the two π -systems for the cyclization without concomitant strain introduction.

Both the increased efficiency of the 5-*endo*-dig cyclization of Ts-substituted radicals and the observed stereoselectivity were fully supported by calculated activation barriers for the cyclizations. The introduction of a sulfonyl group next to the radical center leads to a 2.3 kcal mol⁻¹ decrease in the 5-*endo*-dig activation barrier and switch in regioselectivity toward the formation of the five-membered ring (Table 2).

Several other possible examples of 5-*endo*-dig cyclizations can be found in the literature. Anthony and coworkers¹¹⁸ considered the involvement of a 5-*endo*-dig cyclization as a part of an unprecedented 6-*endo*-dig/5-*endo*-dig cascade leading to a relatively efficient (73% yield, Scheme 24) transformation of a constrained enediyne system into phenanthrene derivatives. Subsequent computational analysis, however, suggested that this transformation is likely to proceed via an alternative mechanism that includes intermolecular attack of Sn-radical at the triple bond, 5-*exo*-dig closure, attack at the aromatic ring and protodestannylation.⁷⁸

Scheme 25 The 5-(π -endo)-endo-dig cyclization of the diradical intermediate formed upon Bergman cyclization.

In addition, Matzger and coworkers^{119,120} reported that a radical cascade initiated by Bergman cycloaromatization can be terminated via a 5-endo-dig closure, albeit in low yields (<2.3%, Scheme 25). Although the dominant process was still the formation of bicyclic reduced product, this important result showed that 5-endo-dig cyclizations are capable of competing (though not very efficiently) with H-abstraction even in the presence of a good H-atom donor (1,4-cyclohexadiene).

The experimental observations agree well with the computed activation barrier for this reaction by Alabugin and Manoharan.⁷⁸ The barrier is decreased (by 4.9 kcal mol^{-1}) to the extent that the cyclization should be able to compete with H-atom abstraction from C–H donors. Most of the decrease comes from the thermodynamic component. Since the radical orbital in the reactant is kept out of conjugation by intramolecular restraints, the system does not need to lose this stabilizing interaction in order to reach the transition state, unlike the above-mentioned systems illustrated in Figure 4d. The transformation

is further aided by the formation of an aromatic benzothiophene moiety, which provides an additional $12\text{--}16\text{ kcal mol}^{-1}$ stabilization to the product. Thus, this example provides the first demonstration of aromatic stabilization being a driving force for 5-endo-dig radical cyclizations. Longer C–S bonds also help in alleviating the geometric requirements in achieving the required attack angle.

4 UNUSUAL PATHWAYS FOR THE FORMATION OF FIVE- AND SIX-MEMBERED RINGS

In this section of the article, we briefly discuss the formation of five- and six-membered rings via an unusual type of radical transformation, which is dramatically different from the traditional radical cyclizations discussed above. A typical radical cyclization conserves the number of radical centers in the bond-forming step. In other words, a radical center is present in *both*

Figure 5 Comparison of radical cyclizations and cycloaromatization reactions. Possible cyclization topologies are shown below together with the suitable starting material needed to give the σ - or π -diradical products.

Figure 6 Four cycloaromatization patterns of enediynes and allene enyne.

the reactant and the product. However, there is a rapidly growing list of unusual cyclizations that transform a closed-shell, nonradical reactant into a *diradical* product (Figure 5). These atypical transformations are referred to as *cycloaromatization reactions*.

These unusual cyclizations occur without the need for external radical initiators because simultaneous *formation* of two radical centers is *coupled* to the bond-forming step. Diradicals are formed in this processes as *two* π -bonds are traded for only *one* σ -bond. This net loss of one chemical bond makes these processes thermodynamically feasible only when an aromatic system is also formed *simultaneously* with the ring closure. Since σ -bond formation and aromatization of the π -system involves two orthogonal π -arrays, cycloaromatization reactions require reactants that contain two alkynes, two cumulenes, or a combination thereof.

Note that σ -radicals are formed through the endo path, whereas exoclosures may produce either a σ -radical, when a triple bond is involved, or

a conjugated π -radical when the new bond is formed at the central carbon of an allene. The most well-known cycloaromatization process is the transformation of (*Z*)-3-ene-1,5-diyne into a *p*-benzynes diradical (the Bergman cyclization¹²¹), which drew significant attention as the key step in the mechanism of biological activity of natural enediyne antibiotics.¹²²

Figure 6 summarizes the cyclizations of the two prototype molecules, (*Z*) hex-3-ene-1,5-diyne and (*Z*) hept-3,5,6-triene-1-yne. In all of these processes, bonds are formed from in-plane π -orbitals in the presence of an orthogonal π -system. However, it is clear that the properties of the newly formed cyclic conjugated systems can be quite different. A new aromatic system is formed only in the Bergman and Myers-Saito cyclizations and thus, in a sense, only these two processes in Figure 8 are bona fide cycloaromatization reactions. However, with proper design, the other two parent cycloaromatization reactions are also possible. Many examples of the “exo-exo” closure (the Schmittel cyclization)

Scheme 26 PET radical anionic C₁–C₅ closure of 1,2-(bistetrafluoropyridine)enediyne.

are known.^{123–126} The “endo–exo” closure is more difficult to accomplish because the parent transformation has been predicted to be $\sim 40 \text{ kcal mol}^{-1}$ endothermic at a high (BCCD(T)/cc-pVDZ) level of theory.¹²⁷ However, recent experimental findings suggest that even this intrinsically unfavorable process is possible.¹²⁸

A number of reviews are available on various aspects of the chemistry and biochemical application of cycloaromatization reactions. Rawat and Zaleski^{129,130} analyzed geometric and electronic properties of metallocenediynes in thermal Bergman cyclizations, while Basak and coworkers¹³¹ concentrated even more closely on the use of enediynyl ligands in chelation-controlled Bergman cyclizations. The Schreiner group¹³² reviewed the application of computational methods toward a variety of cycloaromatization reactions and König and coworkers¹³³ provided a compendium of experimental results related to the electronic effects on the Bergman cyclization. Intricate details of the biological activity of natural enediynes were most recently reviewed by Shen and coworkers,¹³⁴ whereas the medicinal utility of designed enediynes was expertly discussed by Jones and Fouad.¹³⁵ Alabugin and Breiner dissected orbital and electronic effects involved at the different stages of these processes.¹³⁶ Kar and Basak¹³⁷ compared different approaches to selective activation of enediyne prodrugs including photo- and pH-activation, whereas Popik *et al.*¹³⁸ and Alabugin *et al.*¹³⁹ reviewed light-activated cycloaromatization reactions. Research on new structural^{44,140} and electronic^{141–143} effects useful for the control of such processes continues to develop.

The scope of available cycloaromatization reactions increases dramatically when electron-transfer processes are involved. For example, the formation of five-membered radical-anion products benefits from the aromaticity of the cyclopentadienyl anion (Scheme 26).^{144–147} The results of

such reactions are interesting from a practical perspective (*vide infra*). Photoinduced electron transfer (PET)-mediated reductive C₁–C₅ cyclization of a 1,2-(bistetrafluoropyridine) enediyne led to the formation of indenenes with the concomitant formal abstraction of four H-atoms from the environment.¹⁴⁸

Radical anionic cycloaromatization reactions can be controlled via orbital crossings, involving states corresponding to the population of the *in-plane* and *out-of-plane* orbitals. An interesting consequence of such crossings is that the antiaromatic benzene radical-anion core in the reactant regains aromaticity in the product simultaneously with the formation of a new five-membered aromatic moiety, in a process termed *cyclorearomatization*.¹⁴⁹ Because the reductive C₁–C₅ cyclization results in the abstraction of four hydrogen abstractions from the environment as opposed to two in Bergman cyclizations, this new type of cycloaromatization process has been suggested to increase the efficiency of double-strand (ds) DNA damage.^{150–153} Combined with the ability of these molecules to undergo two-photon excitation¹⁵⁴ and target intracellular DNA,¹⁵⁵ the future medical applications of this *cyclorearomatization* process are promising.

5 UNUSUAL CYCLIZATIONS FORMING MEDIUM AND LARGE RINGS

There are no significant strain, stereoelectronic, or thermodynamic obstacles hindering the formation of six-membered rings by standard radical cyclizations. However, as one increases the ring size, a new set of problems arise from entropic factors. The formation of medium-sized rings (8- to 11-membered) is often the most difficult to accomplish,^{21,156} because only a small subset of the reactant conformational space is preorganized for the cyclization. Regarding nucleophilic *exo-tet* cyclizations, Illuminati and

Figure 7 Rate of nucleophilic S_N2 -ring closures with respect to the formed ring size.¹⁵⁶

Mandolini nicely portray the facility of ring formation as a function of size. Of particular interest is the 10^5 increase in rate in going from three- to five-membered ring formation and the million-fold decrease in going from five to eight (Figure 7).¹⁵⁶ Despite this, a variety of methods, including radical closures, have been developed for the synthesis of medium-sized rings. There have been several comprehensive reviews covering the formation of medium- and large-sized rings via radical intermediates.^{157,158}

Porter and coworkers have shown that, in trigonal systems, endoclosure is preferred, particularly

for the smaller cycles (12-*endo*/11-*exo*-trig and 13-*endo*/12-*exo*-trig).¹⁵⁹ The effects of chain length, substituents, and solvent on the rate of endocyclic RCA of ω -(acryloyloxy)polyoxaalkyl radicals¹⁶⁰ has been examined thoroughly in the formation of medium/large macroheterocycles by Beckwith, Maillard, and coworkers (Scheme 27).²¹ While nine-membered ring formation was too slow to compete with reduction, the authors found a large rate enhancement for larger ring formation with respect to the all-carbon acrylate derivative (12-*endo*-trig: 1.5×10^5 vs 4.8×10^3 s⁻¹, respectively).

Eight-membered rings can also be efficiently synthesized by radical closure. Li and coworkers, in their investigations of the effects of Lewis acids (LAs) on the efficiency and stereoselectivity of 8-*endo*-trig closure of carbamoyl radicals, have observed the exclusive formation of an eight-membered ring in a system where 5-*exo*/6-*endo* closure is possible.¹⁶¹ DFT analysis (UB3LYP/6-31G* level) revealed that the competing 7-*exo*-trig cyclization suffered from amide bond distortion in the transition state, accounting for a 4 kcal mol⁻¹ higher barrier than the observed 8-*endo*-trig closure. The chemoselectivity observed (8-*endo* vs 5-*exo*) was determined to stem from the amide bond orientation (Scheme 28). While the calculated barriers are similar (8-*endo*, 10.9 kcal mol⁻¹; 5-*exo*, 10.6 kcal mol⁻¹), the *Z*-rotamer is less stable than the *E*-rotamer and radical cyclizations

Scheme 27 Decrease in regiospecificity as the size of the ring formed increases.

Scheme 28 Regio- and chemoselectivity controlled by amide bond distortion.

Scheme 29 Formation of partially saturated pyrimidine-fused azocine by 8-*endo*-trig closure.

Scheme 30 Necessity of an electrophilic nitrogen in the acyl radical cyclization/ring-expansion pathway.

have been shown to be faster than the amide bond rotation.^{161–163}

Majumdar and coworkers took advantage of the preferential endo-regioselectivity in their synthesis of pyrimidine-fused azocine derivatives. The vinyl radical closed efficiently onto the monosubstituted olefin to give the 8-*endo*-trig product in 70–85% yield, although the authors did not rule out the ring-expansion pathway following 7-*exo*-trig closure (Scheme 29).^{164,165}

Ring expansion has also been observed in the 7-*exo*/8-*endo*-trig closures of acyl radicals (Scheme 30). Bennasar *et al.* discerned that the presence and position of an electron-deficient nitrogen group was critical to the success of radical closure in the formation of indole-fused eight-membered rings.¹⁶⁶ While only the reduced aldehyde was obtained in the absence of the heteroatom, the cyclizations proceeded with complete endo-regioselectivity for the formation of the tricycle. When the nitrogen was in the β -position relative to the indole ring, a 3 : 1 mixture of endo : exo products was obtained. However, this ratio was shifted to yield more of the eight-membered product when the concentration of hydrogen donor was decreased, indicating a rearrangement/ring expansion was occurring.

Chattopadhyay and coworkers have studied the synthesis of oxocines via the 7-, 8- and 9-*endo*-trig closures of aryl radicals. Unactivated alkenes underwent regioselective endo-closures to form fused

tri- and tetracyclic structures with a similar efficiency (60–70%) for 8,5¹⁶⁷ and 8,6¹⁶⁸ fused ring systems. Electron-poor olefins bearing cyano or ester groups on the interior position of the olefin also underwent regioselective endo-closure, generating nine-membered rings in up to 83% (Scheme 31).^{169,170}

In contrast, the cyclizations of aryl radicals onto vinylcyclohexanols and vinylcyclopentanol are sometimes less selective. Ghosh and Ghatak have observed that closure onto the cyclohexyl derivative proceeds regioselectively in a 7-*endo*-trig fashion, giving the tricyclic structure in 68% yield. However, the cyclopentyl starting material provided only the 6-*exo*-trig product in 83% yield (Scheme 32). 8-Endo and 9-*endo*-trig closures occurred regioselectively for both the cyclohexyl and cyclopentyl derivatives.¹⁷¹ *O*-pyridyl radicals were not found to be as selective for the cyclizations of cyclohexanol derivatives, yielding a mixture of 6-*exo* and 7-*endo*-trig products (Scheme 32). However, for the larger systems, as was observed for the aryl radicals, the cyclizations were regioselective for 8- and 9-*endo*-trig closure.¹⁷²

Contrary to the above-mentioned examples featuring a general endo-selectivity, several exocyclic closures have recently been reported. In their synthetic efforts toward ciguatoxin and 51-hydroxy CTX3C, Inoue, Hiram, and coworkers examined the chemoselectivity of radical cyclizations, with competing attacks at an unactivated alkene

Scheme 31 Regioselective endocyclic closure of aryl radicals.

Scheme 32 Regioselectivity of aryl radicals dictated by the size of the cyclic alcohol. Note that *O*-pyridyl radicals lack regioselectivity in this system.

(6-*exo*/7-*endo*) and one which is electron deficient (7-*exo*/8-*endo*). A significant increase in the chemoselectivity, as well as the yield, for 7-*exo*-trig closure was observed when the strength of the electron-withdrawing ester was increased.¹⁷³ Castle *et al.* have shown that 7-*exo*-trig closures onto unactivated monosubstituted olefins are possible, trapping the exocyclic radical in either a 5-*exo* or 6-*exo*-trig closure to give the cascade product in up to 93% yield (Scheme 33).¹⁷⁴

As discussed in the subsequent section, acyl radicals have been utilized in the synthesis of lactams by *N*-philic closure onto imines. Ryu and coworkers have exploited this chemo- and regioselective closure in the synthesis of seven- and eight-membered

lactams by *exo*-trig closure in 69% and 61% yields, respectively (Scheme 34).^{175,176} Bremner and Sengracha have also successfully obtained cyclic amides as a result of 8-*exo*-trig cyclization. The latter regioselectivity was dictated by the formation of a benzylic radical that was trapped either by hydrogen abstraction or aromatization by loss of an adjacent hydrogen atom (Scheme 34).¹⁷⁷

Alves *et al.* observed that benzylic stabilization was sufficient to obtain 10-*exo*-trig closure, as opposed to endocyclic RCA (Scheme 35). The exocyclic benzyl radical was then trapped through hydrogen abstraction and, following a ring-contraction event, the observed imide is obtained in 22%.¹⁷⁸

Scheme 33 7-Exo-trig closure facilitated by either an electron-deficient ester or trapping in a subsequent cyclization.

Scheme 34 Exocyclic closure dictated by the electronics of the transition state (a) and the stability of the cyclic radical (b).

Scheme 35 10-Exo-trig closure forming a benzylic radical.

Additional examples of medium-size ring formation via a CuCl atom-transfer reactions^{179,180} (see **Atom Transfer Radical Polymerization (ATRP) and Addition (ATRA) and Applications**) and titanocene reduction of epoxides¹⁸¹ (see **Epoxides in Titanocene-Mediated and -Catalyzed Radical Reactions**) are known.

6 CYCLIZATIONS PROCEEDING VIA AN UNUSUAL BOND FORMATION

In the previous sections, we discussed cyclizations rendered unusual by the size of a forming ring. However, independent of the size of the ring formed, certain factors disfavor even the well-represented cyclization topologies and are involved in several

Figure 8 Carbon-carbon and carbon-heteroatom bond disconnections for a representative five-membered heterocycle formation by radical cyclization where $Y = \text{CR}_2$, CO, and $X = \text{O}, \text{N}$.

underrepresented bond-forming reactions. In particular, most cycle closures involve carbon-carbon bond formation via carbon radical addition to an alkene or alkyne, whereas radical ring closure via the formation of a carbon-heteroatom bond is relatively scarce. In the following section, we discuss two common approaches to such C-X bond formation: radical closures at the X-end of a $\text{C}=\text{X}$ bond, or cyclizations of heteroatom- (oxygen- or nitrogen-) centered radicals at a $\text{C}=\text{C}$ bond. Both of these methods often enable efficient construction of useful heterocycles (Figure 8).

6.1 Oxygen- and Nitrogen-Centered Radical Closures

In our discussion of cyclizations mediated via the carbon-heteroatom bond formation, we limit ourselves to the formation of C-O and C-N bonds. We first discuss trigonal and digonal cyclizations of heteroatomic radicals in comparison with the more common carbon derivatives, followed by closures of carbon radicals onto the heteroatom of a $\text{C}=\text{X}$ bond, referred to as X-philic closures (Figure 9, $X = \text{O}, \text{N}$).

6.1.1 Nitrogen-Centered Radicals

The rate of 5-*exo*-trig cyclization of *N*-methylpent-4-enylaminyl radical has been found to lie in the

Figure 9 Unusual cyclizations proceeding through the formation of a carbon-nitrogen or carbon-oxygen bond.

range of 3×10^3 to $4 \times 10^4 \text{ s}^{-1}$,^{182–187} 1–2 orders of magnitude slower than that of the 5-hexenyl radical ($2 \times 10^5 \text{ s}^{-1}$).¹⁸⁸ The rate can be accelerated by the addition of a catalytic amount of an LA. However, high LA concentrations have a detrimental effect, possibly owing to disruption of the chain propagation step or to activation of the cyclic radical for nucleophilic attack and degradation.¹⁸⁹ This coordination has no effect, however, on the *exo* regioselectivity of closure. As the electrophilicity of nitrogen radicals increases, for example, amidyl radicals, the rate of 5-*exo*-trig closure becomes 3–4 orders of magnitude *faster* than the carbon species (5×10^8 to $2 \times 10^9 \text{ s}^{-1}$).²⁰

The activation barriers (UB3LYP/6-311++G**//UB3LYP/6-31G* level) for 5-*exo* closure of a primary aminyl radical in the parent trigonal systems are slightly lower ($10.2 \text{ kcal mol}^{-1}$) than endocyclic closure ($12.1 \text{ kcal mol}^{-1}$).¹⁸² The regioselectivity can be tuned, as with carbon-centered radicals (*vide supra*), by stabilizing groups on the interior position of the alkene. The observed selectivity, and calculated activation energies, begin to favor 6-*endo*-trig closure with increasing steric bulk in the δ -position. Through introduction of a strongly stabilizing group, such as chloro or phenyl, the barrier of closure is 2.3 and $3.8 \text{ kcal mol}^{-1}$,

Figure 10 Observed regioselectivities and calculated activation barriers (in parentheses) for the cyclizations of primary nitrogen radicals (kcal mol⁻¹, UB3LYP/6-311++G**/UB3LYP/6-31G* level, Ref. 182).

respectively, lower for endocyclic closure with observed regioselectivities greater than 93% (Figure 10).¹⁸² The respective digonal system has yet to be investigated.

The rates and regioselectivities for the competition of 5-*exo*-trig and 6-*endo*-trig of aminyl radicals are well documented. This competition exhibits an inherent preference for 5-*exo*-cyclic closure.^{182, 190–194} Although there are numerous examples of nitrogen-centered radical cyclization reactions with olefins,^{195–198} to the best of our knowledge, there are very few isolated examples of a nitrogen radical closure onto an sp carbon. A nitrogen-centered 5-*endo*-dig cyclization has been proposed by Montevecchi and Navacchia for the formation of indole products from the reaction of *O*-(1-pentynyl)aniline with phenylthiol and AIBN. In the absence of a good hydrogen donor (heat, PhSSPh), the indole product was obtained in 90% yield (45% conversion, Scheme 36).¹⁹⁹

In their studies of the intramolecular reductions of *N*-stannyl aminyl radicals, Kim and coworkers observed an unexpected cyclic by-product. This minor product (27%) resulted from a competitive 6-*exo*-dig cyclization of the aminyl radical onto the carbon of the nitrile.²⁰⁰ This work was later expanded by Leardini, Spagnolo, and coworkers

who examined the cyclizations of both aliphatic and benzylic azides, obtaining up to 66% yield for the 5-*exo*-dig product (Scheme 37). In an attempt to elucidate the radical nature of the reaction, the authors attached a pendant alkene to trap the iminyl radical, successfully yielding the bicyclic product in up to 88% yield (6-*exo*-dig and 5-*exo*-trig).²⁰¹

6.1.2 Iminyl Radicals

Zard has published several reviews covering the chemistry of iminyl radicals, most recently in 2008.^{202,203} While the rate of 5-*exo*-trig closure of 2-methyl-6,6-diphenyl-5-hexeniminyl radical has been found to be 10-fold faster than the respective secondary aminyl radical (2×10^6 vs 3×10^5 s⁻¹, respectively, Scheme 38), the secondary carbon derivative still proceeds at a faster rate (2×10^7 s⁻¹).¹⁹ These radical species are often generated from the heterolytic cleavage of such species as sulfenimides,^{204,205} oximes,^{206–209} and *N*-thiocarbonylhydrazones,²¹⁰ and can even result from hydrogen-atom abstraction alpha to an azide followed by loss of N₂.²¹¹ They are also found within cascades, resulting from radical addition to nitrile groups.^{212,213}

6.1.3 Oxygen-Centered Radicals

Small rings can be formed via trigonal closure of oxygen radicals (Scheme 39). Amaudrut and Wiest have shown that epoxides can not only be formed by 3-*exo*-trig closure, but trapped successfully by an arylthiyl radical when the olefin is substituted with a phenyl group.²¹⁴ Computational analysis revealed that the closed oxiranylbenzyl radical is preferred to the open cinnamyloxy radical by 5.1 kcal mol⁻¹ (B3LYP/6-31G* level). These results not only support the notion^{215,216} that the ring-opening of the oxiranyl methyl radical is thermodynamically

Scheme 36 5-*Endo*-dig closure of an N-centered radical.

Scheme 37 Cyclizations of aminyl radicals onto sp-hybridized carbons.

Scheme 38 5-Exo-trig closure of an iminyl radical.

Scheme 39 3-Exo-trig closure of an alkoxy radical trapped by atom transfer.

governed but also allowed for the estimation of the lower limit of the rate constant for 3-*exo*-trig of an oxygen-centered radical ($k_c = 3.2 \times 10^{10} \text{ s}^{-1}$).²¹⁴ In the absence of the phenyl group, the oxiranyl carbinyl radical can be trapped by *t*-butyl nitrite and detected by electron spin resonance (ESR) spectroscopy.²¹⁷

Hartung has thoroughly analyzed the trigonal cyclizations of oxygen radicals, particularly the competition between 5-*exo* and 6-*endo*-trig closures.²¹⁸ Interestingly, while the angles of attack for 5-*exo* and 6-*endo* for the parent 4-pentenyl-1-oxy radical are quite similar (99° and 93° , respectively, UB3LYP/6-31+G* level,

Scheme 40 (a) Calculated angles of attack and observed trends regarding substituents effect on stereoselectivity for alkoxy radicals. (b) Chemoselective closure onto the *Z*-vinylsilyl ether.

Scheme 40),²¹⁹ the alkoxy radical closes regioselectively on the parent system to give a 98 : 2 ratio of 5-*exo*: 6-*endo* products.²²⁰ The rate constant for 5-*exo*-trig closure has been calculated to be $5.2 \times 10^8 \text{ s}^{-1}$ (80 °C).¹⁸ The regioselectivity begins to deteriorate as steric bulk increases at the δ -position. Upon introduction of a phenyl group, the regioselectivity is completely reversed, giving a 7:93 ratio of *exo*:*endo* products.²¹⁹ Hartung and coworkers have derived general guidelines regarding the stereoselectivity of these closures, where 1- and 3-alkyl-substituted pent-en-yl-1-oxy radicals yield *trans*-tetrahydrofurans preferentially and substitution at position 2 gives *cis* products.^{220,221} The cyclizations of oxygen-centered radicals can also be chemoselective, as shown by the work of Sammis, who observed selective 5-*exo*-trig closure onto the *Z*-vinylsilyl ether as opposed to the monosubstituted olefin (Scheme 40).²²²

6.2 O- and N-Philic Radical Closures

6.2.1 N-Philic Closure

The chemoselective addition of carbon-centered radicals to the carbon of imines,^{223,224} proceeds at the position with the larger LUMO coefficient.²²⁵ The regioselectivity appears to be kinetically favored,

as shown by the *ab initio* calculations of Ryu and Komatsu (*vide infra*).^{224,226} However, regioselective closure onto the nitrogen, called *N*-philic closure, can be achieved by manipulation of the electronics of both the radical species as well as the carbon–nitrogen π -bond. These closures can result in both *exo*- and *endocyclic* closure depending on whether the nitrogen is in the interior or exterior position of the C=N bond.

Handa and Rose²²⁷ expanded the work of Han and Frey,²²⁸ also observing complete regioselectivity for 3-*exo*-trig closure onto the nitrogen of aldimines (Scheme 41). Bowman and coworkers thoroughly examined the cyclizations of primary carbon radicals onto aldimines for the 4-*exo*/5-*endo*, 5-*exo*/6-*endo*, and 6-*exo*/7-*endo* pairs.^{229,230} While the authors were unable to isolate any cyclic products for either imine variant for small ring formation (4-*exo*/5-*endo*), a strong stereoelectronic preference for exocyclic closure was observed for the 5/6 competition, regardless of the position of the nitrogen or the stabilizing effects of the substituent. The study of 6/7 was marred by competing 1,5-*H* abstraction. While primary carbon radicals were not found to undergo 4-*exo*-trig or 5-*endo*-trig closure, Tanner and Rahimi have reported a rare example of a 5-*endo*-trig cyclization where a 3° radical regioselectively closes onto the nitrogen of a ketimine (Scheme 41).²³¹

The 5-*exo*-trig closure of an sp^3 carbon radical onto the nitrogen of an ketimine is reversible,

Scheme 41 3-Exo-trig and 5-endo-trig *N*-philic closure of carbon-centered radicals.

Scheme 42 Steric and electronic control of cyclic isomerization.

and the degree of isomerization can be controlled by both sterics and electronics (Scheme 42). Johnston *et al.*²³² observed a loss in enantiomeric excess with increasing steric strain *ortho* to the formed ring. The isomerization equilibrium can also be shifted by electronic effects on the ketimine—the cyclic α -aminyl radical is stabilized by electron-withdrawing groups and destabilized by electron-donating substituents. A higher degree of racemization is observed in the latter case.

The regiochemical preference for both vinyl^{233–235} and acyl^{236,237} radical closure onto olefins is that of exocyclic closure. However, the paths of the two radical species diverge when the olefin is exchanged for an imine. Ryu, Komatsu, and coworkers examined the cyclizations of vinyl radicals onto aldimines, observing regioselective

6-*endo*-trig closure onto the carbon of the C=N bond.²²⁶ Ketimines, however, resulted only in hydrostannylation (Scheme 43). The thermodynamic stability of the cyclic radicals was found to be similar (−32.7 and −33.1 kcal mol^{−1} for 5-*exo* and 6-*endo*, respectively, at UHF/3-21G level of theory). The regioselectivity is believed to arise from the kinetic preference caused by the 3.4 kcal mol^{−1} lower TS for endocyclic closure.²²⁶ This regioselectivity can be reversed if sufficient stabilization is provided for the 5-*exo* cyclic radical, as shown by the imine derived from acetophenone.²³⁸

Reactions of aryl radicals with aldimines proceed differently from the reactions with ketimines. Similarly to vinyl radicals, aryl radicals preferentially close at the carbon of aldimines.^{239–243} However,

Scheme 43 Closure of π -*exo* and π -*endo* vinyl radicals onto aldimines and ketimines.

Scheme 44 Change in regioselectivity of aryl radicals between aldimines and ketimines.

the ketimine derivative has been shown to have the opposite regioselectivity, closing in a 5-*exo*-trig fashion onto the nitrogen to give the stable tertiary, benzylic radical (Scheme 44). The nature of the radical-stabilizing aryl group (electron-donating, electron-withdrawing) was found to have little effect on the regioselectivity.²⁴⁴ Orito *et al.* have shown that more unusual ring-closure pathways (5-*endo*-trig) can be successfully achieved with aryl radicals and ketimines (Scheme 44).²⁴⁵

As discussed above, the cyclizations of aryl and vinyl radicals preferentially cyclize onto the carbon of an imine system. However, when the sp^2 carbon is part of a C=O double bond, a complete reversal in the regioselectivity is observed (Scheme 45).²⁴⁶

This holds true for the formation of monocyclic, bicyclic, and benzo-lactams,²⁴⁷ the only exception being closure onto hydrazones.²⁴⁸ Ryu *et al.* have

Scheme 45 C- versus N-philic regioselectivity for radical 5-*exo*-/6-*endo*-trig cyclizations of vinyl and acyl radicals.

shown that the exocyclic closure of acyl radicals onto imines can be used to successfully to form four-, five-, six-, seven-, and eight-membered lactams (Scheme 46).^{175,176} The regioselectivity of

6.2.2 O-Philic Closures

The closure onto the oxygen of a carbonyl moiety is far less represented in the literature than the nitrogen examples discussed in the previous section. Lactones can be synthesized via an *O*-philic radical cyclization/elimination reaction. Kraus and Landgrebe studied the reactions of iodostannyl esters with a series of alkenes in the presence of a catalytic amount of AIBN and observed up to 78% yield for the corresponding lactone (Scheme 47). There are, however, two possible reaction pathways that proceed to the product following the initial addition, cyclization onto the carbonyl followed by fragmentation to form the lactone and tin radical, or an S_H1 closure onto the sp^3 oxygen.²⁵⁵ The formation of lactones from 1°-carbon radical cyclization onto methyl esters (with loss of methyl radical) have also observed, however in low yields.^{256,257} Aryl radicals, however, do not undergo *O*-philic 5-*endo*-trig closure onto *ortho*-acetate groups.^{258,259}

Carbon radicals have also been found to attack the oxygen of a peroxide bond, yielding epoxides and alkoxy radicals, with rates of 3-*exo*-tet closure ranging from $7.6 \times 10^3 \text{ s}^{-1}$ for stabilized benzylic radicals to $2.9 \times 10^7 \text{ s}^{-1}$ for a cyclooctyl radical.¹³ Davies and coworkers have studied these closures using ESR spectroscopy, and found that the rate of 3-*exo*-tet closure was greatly accelerated when *gem*-dimethyl groups were present (Scheme 48).²⁶⁰

As early as 1964, Menapace and Kuivila found that 2-phenyltetrahydrofuran was formed upon reaction of γ -chlorobutyrophenone with $\text{Bu}_3\text{SnH/AIBN}$ in 52% yield, along with 13% of butyrophenone.²⁶¹ Mendenhall, Luszyk, and workers examined the cyclizations of 2-formylbenzoyl radical and observed complete regioselectivity for closure onto the oxygen atom of the formyl group, with no evidence of the 4-exo alkoxyl radical by ESR, laser flash photolysis (LFP), or trapping

Scheme 47 Irreversible *O*-philic closure by 5-endo-trig cyclization/fragmentation closure.

Scheme 48 Rates of 3-*exo*-tet *O*-philic closures as a function of substitution α to the acyclic radical.

studies. The rate of 5-endo closure was found to be much faster than expected ($2 \times 10^8 \text{ s}^{-1}$).¹⁷ The activation barrier for this closure was calculated to be $12.4 \text{ kcal mol}^{-1}$ by Eguchi *et al.* (UHF/6-31G* level). However, the authors proposed that the

closure of conjugated acyl radicals onto the oxygen of a carbonyl moiety proceeds through a nonradical mechanism, as the SOMO was calculated to be perpendicular to the molecular plane and does not change throughout the course of the reaction. The

Scheme 49 Experimental *O*-philic closure of carbon and acyl radicals (a) and computational analysis of related systems in kcal mol^{-1} (b).

proposed ring-closure pathway consists of the addition of the lone pair of the oxygen to the carbon of the stabilized ketene-substituted α -carbonyl radical ($E_a = 9.7 \text{ kcal mol}^{-1}$, $\Delta E = -11.2 \text{ kcal mol}^{-1}$). The authors also examined the 5-*endo*-trig closure of the saturated derivative as well as the primary carbon radical and while both cyclizations have large activation barriers (33.4, 44.1 kcal mol^{-1} , respectively), the acyl radical derivative is considerably more exothermic ($\Delta E = -12.6$ and $-1.6 \text{ kcal mol}^{-1}$, respectively, Scheme 49).²⁶² The large barriers and low exothermicity, particularly for the alkyl radical, may be one of the reasons why *O*-philic closures remain underrepresented.

7 CONCLUSION

Enthalpic and entropic factors conspire against unusual radical cyclizations. However, these obstacles can be overcome via judicious choice of reaction conditions, use of the Thorpe–Ingold effect, destabilization of reactants and stabilization of the cyclic products, coupling of thermodynamically unfavorable ring closures with highly exothermic follow-up steps, as well as control of the electronic interactions of the reacting centers. In addition, electron-transfer and photochemical processes can bypass energetic obstacles that make cyclizations of neutral molecules in their ground state difficult.

Modern computational methods start to play a more important role in the discovery of new radical cyclizations, providing a useful alternative to chemical intuition. Quantitative information on the potential energy surfaces involved in radical cyclizations point to possible ways to avoid the bottlenecks associated with the intrinsic stereoelectronic preferences and unfavorable thermodynamics of such processes. Once the limitations are understood and the energy landscape is carefully mapped, new and creative ways for traversing this rugged terrain can be charted.

1 INTRODUCTION

Cascade reactions, understood as transformations allowing the formation of multiple bonds under the same reaction conditions, represent one of the most challenging and fascinating aspects of radical chemistry. Employed in numerous syntheses of natural products,¹ they embody control over chemical reactivities. Furthermore, they contribute to progress toward green chemistry since they allow a large increase in molecular complexity in a minimum of steps, and hence waste generation.

Since the addition of a radical onto an unsaturation generates a new radical species that can further react, organic radicals are inherently prone to engage in cascade reactions. Besides, radical transformations generally occur under mild conditions, which avoid the requirement of protection/deprotection steps and allow access to high stereocontrol.^{2–4} Organic radicals are thus tools of choice for the development of efficient and selective cascade reactions as demonstrated by the huge number of applications reported in the literature.^{5–9}

Cascade radical reactions have been reviewed in depth by our group in 2006,¹⁰ so only the literature starting from this year will be covered in this account. Even if clear-cut classification is often difficult, we will separate the cascades occurring via a chain radical process from those involving

non-chain redox processes implying organometallic species.

2 CASCADE REACTIONS INVOLVING CHAIN RADICAL PROCESSES

2.1 Intramolecular Processes

The most widespread application of radical cascades is the construction of polycyclic compounds from polyunsaturated precursors via several intramolecular steps. These unimolecular processes consist mostly of reductive cyclizations but can also include less usual radical steps such as homolytic substitutions, fragmentations, and translocations. This review is subdivided according to the type of processes involved.

2.1.1 Cascade Reactions Involving Polycyclizations Only

As early as 1976, Baldwin's rules based on stereochemical requirements have given helpful guidance to predict the favored cyclization mode and design suitable precursors. Poly 5- or 6-exo cyclizations are the most straightforward strategies for the construction of polycyclic frameworks. In a synthetic study toward azadirachtin, Watanabe

Figure 1 Stereoselective radical cascade as a key step in the construction of AB rings of azadirachtin.

employed a cascade involving 5-*exo*-dig/6-*exo*-trig radical cyclization using a tetrasubstituted allene and an α,β -unsaturated lactone as radical acceptors.¹¹ The rigidity of the spirolactone ring embedded in the precursor seemed to favor the cyclization and allowed the synthesis of the two key carbocycles of the target molecule in a diastereoselective manner and with an excellent 90% yield (Figure 1). An efficient synthesis of angularly fused carbocycles by a combination of 5-*exo*-dig and 5-*exo*-trig cyclizations was described by Mohanakrishnan.¹²

The presence of heteroatoms in the linkage is generally well tolerated and allows the smooth synthesis of heterocycles.^{13,14} Another elegant strategy to access these frameworks is the use of heteroatom-containing acceptors. *O*-benzyl oxime seems to be a particularly suitable partner since the 5-*exo* cyclization rate of an alkyl radical on this moiety ($k_{5\text{-exo}} = 4.2 \times 10^7 \text{ s}^{-1}$ at 80 °C)¹⁵ is two orders of magnitude higher than the cyclization on an alkene and one order higher than the cyclization on an imine ($k_{5\text{-exo}} = 6.0 \times 10^6 \text{ s}^{-1}$ at 80 °C).¹⁶ A

synthesis of tricyclic pyrrolidines via a radical cascade employing *O*-benzyloximes was described by Jaramillo-Gómez (Figure 2).¹⁷ Treatment of precursor **1** with Bu₃SnH and 2,2-azo-bis-isobutyronitrile (AIBN) generates aryl radical **2**, which adds to the electrophilic carbon of the oxime ether. The alkyl-oxyaminyl radical **3** formed cyclizes onto an electron-poor olefin to give the tricyclic compound **4** after reduction.

Heterocyclic frameworks can also be built by radical cascades starting with heteroatom-centered radicals, as illustrated by Zard. Employing hydroxamic benzoates as amidyl radical precursors, he developed a new access toward indolizidine and pyrrolizidine skeletons via radical cascades.^{18,19} Interestingly, the mode of cyclization, for example, 5-*exo*-trig/5-*exo*-trig or 5-*exo*-trig/6-*endo*-trig, is completely directed by the absence or presence of a chlorine substituent on the second double bond (Figure 3).

As demonstrated by the latter example, 6-*endo* can become the favored mode of cyclization with

Figure 2 Synthesis of tricyclic pyrrolidine employing oxime ethers as radical partners.

Figure 3 Access to indolizidine and pyrrolizidine skeletons by radical cascades triggered by amidyl radicals.

specifically designed substrates. Hishibashi has, for instance, shown that the 6-*endo*-trig selectivity of radical cyclization onto the double bond of enamides could be determined by the position of the carbonyl group.^{20,21} He used this selective cyclization in combination with a 5-*endo*-trig cyclization to afford a concise synthesis of cyclindricine skeleton (Figure 4).

Using a similar substrate-directed strategy, Hishibashi developed several radical cascades

involving first a 7-*endo*-trig cyclization onto the double bond of an enamide followed by 5-*endo*-trig cyclization of the α -amidoyl radical generated.^{22–24} Selective 7-*endo*-trig cyclization in a radical cascade was also achieved by Kahne for the synthesis of norbornyl-based tetracyclic amine, presumably owing to the inherent preorganization of the precursor and the stability of the radical intermediate formed.²⁵

Figure 4 Synthesis of cyclindricine skeleton via two consecutive endo-selective cyclizations.

Castle cleverly exploited the slower reduction rate of acyl radicals²⁶ to develop a radical cascade featuring a 7-*exo*-trig cyclization followed by a 6-*exo*-trig cyclization.²⁷ Thus, treatment of selenoester **5** with tris(trimethylsilyl)silane in the presence of Et₃B and air allows the generation of acyl radical **6** that cyclizes under a 7-*exo*-trig mode to give alkyl radical **7**. 6-*exo*-trig Cyclization and final reduction afford the bicyclo[5.4.0]undecane ring **8**, a structural motif present in the framework of anticancer alkaloid Lyconadin A (Figure 5). It is noteworthy that the use of a faster hydrogen donor

Figure 5 7-*exo*/6-*exo* Cyclization triggered by an acyl radical.

such as Bu₃SnH instead of (TMS)₃SiH resulted in a complex mixture probably because of abortive reductions.

Radical transannulation reactions, leading to the construction of bonds between atoms on opposite sides of a ring, occur favorably in medium and large cycles. Sequential macrocyclization/transannulation reactions thus offer unique opportunities for the fast synthesis of ring-fused systems, such as those found in the structure of terpenoids, taxoids, and steroids.²⁸ Pattenden developed the use of ynones as radical acceptors for the macrocyclization step (Figure 6). This approach allowed him to access efficiently the 6,8,6-ring fused taxane system via a 12-*endo*-dig/6-*exo*-trig radical cascade.²⁹ More recently, he examined new applications toward the elaboration of the oestrane ring.^{30–32} Upon treatment of precursor **9** with Bu₃SnH and AIBN, he did not obtain the expected macrocyclization/radical Diels–Alder cascade reaction but an original cascade process leading to tetracyclic dihydrofuran **12**. Initial 13-*endo*-dig macrocyclization generates vinyl radical **10**, which adds to the furan ring. Allylic migration of the radical **11** formed leads to a stabilized benzylic radical, which is finally reduced.

2.1.2 Cascade Reactions Involving Fragmentation/Cyclization Steps

Ring-opening fragmentations with concomitant release of strain are particularly attractive steps in radical cascades since they generally lead to the formation of a double bond that can act as a new acceptor. Cyclopropyl methyl radical fragmentation is extremely fast ($k = 1.2 \times 10^8 \text{ s}^{-1}$ at 37 °C³³) and has consequently found the most significant number of applications in radical cascade reactions.³⁴ Pattenden recently disclosed a new synthetic approach toward C-nor-D-homosteroid ring system via consecutive macrocyclization, cyclopropane ring-opening, and transannular reactions.³⁵ Starting from seleno ester precursor **13**, the corresponding acyl radical **14** is generated and cyclizes in a 13-*endo*-trig manner onto the vinylcyclopropane. Ring opening delivers the benzylic radical **15**. Sequential 5-*exo*-trig and 6-*exo*-trig transannular cyclizations lead to a 1:1 mixture of C10 methyl epimers of the desired tetracyclic core **16** (Figure 7). This work was the first report

Figure 6 Use of an ynone acceptor in a macrocyclization/transannulation sequence.

Figure 7 Cascade reaction involving macrocyclization, cyclopropane ring opening, and transannulation triggered by an acyl radical.

of a macrocyclization/transannulation sequence triggered by an acyl radical.

The regioselectivity of the cyclopropyl-homoallyl radical rearrangement in azabicyclic systems has

been thoroughly studied by Hodgson. He found that the stabilization of radicals in the α position of nitrogen drove the selectivity of the skeletal rearrangements efficiently.³⁶ He applied this

Figure 8 Radical cascade using methyleneaziridine.

strategy to the synthesis of various azabicyclic frameworks via radical decarboxylation–homoallylic rearrangement–reduction sequences.^{37,38}

Rings other than cyclopropanes can be fragmented when stereoelectronic factors favor the ring-opening reaction.³⁹ Thus, Shipman demonstrated that the strain energy associated with the methyleneaziridine ring (12–13 kcal mol^{−1} more ring strain than simple aziridine⁴⁰) allowed the

development of new radical rearrangements.⁴¹ For instance, he disclosed a sequence involving 5-*exo*-trig cyclization, C–N bond fission of aziridinylcarbiny radical, and second 5-*exo*-trig cyclization leading to the indolizidine framework (Figure 8).⁴²

Since alkoxy radicals fragment easily,⁴³ ring opening of cycloalkoxy radicals is an efficient way to obtain skeletal rearrangements.

Figure 9 Cascade synthesis of hydroazulenone via alkoxy radical fragmentations.

Figure 10 Approach to fused polycyclic cyclopropane via radical cascade reaction involving cyclizations– β -elimination of chloride.

Kawahara reported an elegant cascade synthesis of hydroazulenone **22** from epoxy-hydroindan **17** via alkoxy radical fragmentation.⁴⁴ A plausible mechanism is depicted in Figure 9. Treatment of precursor **17** with Bu_3SnH and AIBN forms methyl radical **18**, which rearranges to alkoxy radical **19** through epoxide ring opening. Fragmentation affords the nine-membered ring intermediate **20**. 5-*exo*-trig Transannular cyclization and subsequent 3-*exo*-trig on the carbonyl moiety generates a second alkoxy radical **21** that fragments to give the hydroazulene core in 60% yield. Since the reports of Kawahara⁴⁴ and Renaud,^{45,46} applications of alkoxy radical fragmentation in purely radical cascades have been scarce, but beautiful examples using single-electron transfer reagents have been published (see Section 3).

β -Elimination steps can elegantly terminate radical cascades and prevent undesired rearrangements, when the kinetics involved is suitably matched. Our group thus reported the synthesis of fused polycyclic vinylcyclopropanes via a radical cascade terminated by β -elimination of chloride.⁴⁷ The approach employs (dichloromethyl)dimethylsilyl ether as the point of both initiation and termination of the radical cascade reaction. Treatment of homoallylic propargyl ether **23** with Ph_3SnH , AIBN, and triethylamine as HCl scavenger generates α -silyl radical **24**. The latter undergoes successive 5-*exo*-dig, 5-*exo*-trig, and 3-*exo*-trig cyclizations. The fast β -elimination of chloride avoids the retro-fragmentation of cyclopropane and affords tricyclic product **25**, which is

immediately quenched with MeLi to provide the silylated alcohol **26** in overall excellent yield and diastereoselectivity (Figure 10). Parker reported the enantioselective synthesis of (–)dihydroisocodeine using a cascade radical cyclization terminated by the β -elimination of a thiophenyl radical as a key step.⁴⁸

2.1.3 Cascade Reactions Involving Translocation/Cyclization Steps

Intramolecular hydrogen transfer reactions are often considered as undesired side reactions; however when introduced in a controlled manner in radical cascades, they open the way to exciting new possibilities. Indeed, they allow the functionalization of remote unreactive positions by extremely selective C–H activations.

The most commonly employed process is the rearrangement of highly reactive vinyl radical to a more stable alkyl radical via 1,5-H transfer. The resulting translocated radical is then perfectly placed to perform rapid 5-*exo*-trig cyclization. Such cascade translocation/cyclization of vinyl radicals has been elegantly employed in the preparation of various five-membered rings and has been recently reviewed in depth by Renaud.⁴⁹ Our group reported a synthesis of cyclopentanol derivatives via cascade 5-*exo*-dig cyclization of α -silyl radical, diastereoselective 1,5(π -*exo*)-H-transfer on the vinyl radical formed, and 5-*endo*-trig cyclization.⁵⁰

Figure 11 Construction of tetrahydrofuran core of (-)-amphidinolide K via radical relay cyclization.

Another way to exploit 1,5-H transfer in cascades is radical relay cyclizations initiated by oxygen-centered radicals. Sammis recently reported a beautiful methodology applied to the synthesis of the tetrahydrofuran core of (-)-amphidinolide K.⁵¹ *N*-Alkoxyphthalimide **27** is used as a precursor for alkoxyradical **28**, which undergoes 1,5-hydrogen abstraction (Figure 11). The resulting alkyl radical **29** is perfectly placed to cyclize onto the terminal alkyne. Conveniently, this strategy is effective for

the synthesis of five- and six-membered carbocycles or heterocycles starting from the suitable linear precursor.

1,6-Hydrogen transfer requires a disfavored seven-membered ring transition state. It is thus a far less common translocation. However, it can become a major pathway when conformational bias and stabilizing effects are adequately positioned. Reisert has reported a cascade 1,6-hydrogen transfer and 5-*exo*-trig cyclization of the allylic radical

Figure 12 Cascade synthesis of 3,3,3 propellane ring system triggered by homolytic substitution at sulfur.

generated for the synthesis of 2,3-disubstituted dihydrobenzofurans.⁵²

2.1.4 Cascade Reactions Involving Homolytic Substitution/Cyclization Steps

Intramolecular homolytic substitution at the sulfur atom can provide an efficient trigger for radical cascades, as reported by Crich (see **Intramolecular Homolytic Substitutions in Synthesis**).⁵³ This strategy is especially useful for the generation of radicals that are difficult to form with standard approaches. Thus, in a sophisticated cascade synthesis of the propellane ring system, Patten den used a iodoaryl-thioester as a precursor for the desired α,β -unsaturated acyl radical.^{54,55} Once generated by homolytic substitution at sulfur, the α,β -unsaturated acyl radical **30** undergoes cascade 5-*exo*-trig and 5-*endo*-dig cyclizations via its corresponding α -ketenyl alkyl radical resonance form **31** to afford the desired tricyclic ketone **32** (Figure 12).

Aromatic homolytic substitution refers to the addition of a radical to an aromatic ring with subsequent rearomatization through the loss of a leaving group (see **Radical Arylations**). The involvement of this type of step in radical cascades offers interesting possibilities for the synthesis of polycyclic products containing fused aromatic rings.⁵⁶

In most of the cases, the leaving group is hydrogen, and the mechanistic details of rearomatization

are still unclear. Several mechanistic studies have been performed, leading to the conclusion that various pathways could be involved according to the conditions, and that the initiator or the dioxygen present in the reaction mixture could be responsible for the required hydrogen abstraction.⁵⁷ A short synthesis of tetracyclic alkaloid lennoxamine was achieved by Ishibashi through aryl radical-induced 7-*endo*-trig cyclization on enamide and subsequent homolytic aromatic substitution on a dimethoxyphenyl group.⁵⁸

Bowman developed the cyclization of vinyl radicals onto suitably placed nitrile groups followed by aromatic homolytic substitutions by the iminyl radicals generated. He proposed that in his case, the final H-abstraction step was performed by either the *tert*-butoxyl radical or the methyl radical generated from hexamethylditin. Using this strategy, he reported the efficient cascade synthesis of biologically active mappicine and luotonin A.⁵⁹ Another cascade synthesis of luotonin A under tin-free conditions was developed in our group using *N*-acylcyanamide moiety as the original radical partner (Figure 13).⁶⁰ Irradiation generates quinolinyl radical **33**, which cyclizes onto the cyanamide to form an amide-iminyl radical **34**. Density functional theory (DFT) calculations and experimental data suggest that the aromatic homolytic substitution occurs via a 6-*endo* addition rather than via an *ipso* substitution followed by a neophyl rearrangement. Final rearomatization is presumably induced by dioxygen.

Figure 13 Synthesis of luotonin A via consecutive cyclization/aromatic homolytic substitution reactions.

Figure 14 Synthesis of the pentacycle core of fortucine via a cascade cyclization/aromatic homolytic substitution reaction triggered by an amidyl radical.

The initiation of radical cascades by nitrogen-centered radicals is always challenging since these species are often less reactive than their carbon counterparts. However, they provide beautiful entries toward polycyclic alkaloids, as illustrated by Zard with the synthesis of ($\pm$)-fortucine.^{61,62} Treatment of precursor **35** with dilauroyl peroxide (DLP) delivers amidyl radical **36**, which undergoes a 5-*exo*-trig cyclization followed by aromatic homolytic substitution. The cascade is regio- (14:1 para/ortho ratio with respect to the benzyloxy group) and stereoselective (Figure 14). Aminyl radicals generated from the corresponding azides were employed by our group in radical cascades involving consecutive 5-, 6- or 7-*exo*-dig cyclizations on *N*-acyl cyanamides and aromatic homolytic substitutions, providing the first radical synthesis of guanidines.⁶³

In less widespread cases, the aromatic homolytic substitution occurs on a carbon bearing a substituent, leading to the extrusion of a carbon- or heteroatom-centered radical. Cascades beginning with the addition of an aryl radical to *N*-acylcyanamide and ending with the displacement of methyl, methoxy, and fluorine radicals from an aromatic carbon were reported by our

group.⁶⁴ DFT calculations were performed to gain insights into the mechanism of these extrusions. A possible transition state for the departure of the methyl radical was proposed (14.6 kcal mol⁻¹), in which the cost of breaking the C–C bond is minimal compared to normal values. Interestingly, when the initial radical was switched from aryl to vinyl, it was possible to trap the extruded substituents via addition onto the suitably placed double bond (Figure 15).⁶⁵ Hydrogen and carbon substituents, such as methyl, isopropyl, and trifluoromethyl, were found to undergo this unprecedented complex migration whose mechanism was studied thanks to deuteration experiments. Hydrogen migration was found to probably occur via a bimolecular exchange.

Another possibility is that the leaving group is linked to the chain connecting the radical and the arene undergoing addition. The homolytic substitution can then be followed by other intramolecular radical steps, as exemplified by Robertson.⁶⁶ He proposes that when vinyl radical **37** cyclizes onto the aryl ring via an ipso mechanism, rearomatization occurs with extrusion of a carbamoyl radical **38**. The latter is thought to undergo a second aromatic homolytic substitution to yield phthalimide **39** (Figure 16).

Figure 15 New cascades involving homolytic substitution at ortho-substituted benzoyl ring in the cases of aryl and vinyl radical precursors.

Figure 16 Radical cascades for the synthesis of substituted phthalimides through cascade homolytic substitutions/fragmentation reactions.

2.2 Cascade Reactions Involving Both Intra- and Intermolecular Steps

This reactivity has also been recently highlighted in detail in the related sections of reviews by Rowlands^{8,9} and Majumdar.⁶⁷

2.2.1 Sequences Involving Formation of Five-Membered Rings

Renaud and coworkers found that benzenesulfonyl azide is a suitable reagent to conduct an azido-sulfonylation reaction when the process is coupled with a fast cyclization (see **Unusual Radical Acceptors**).⁶⁸ They reported an efficient cascade

in which 1,6-dienes or enynes undergo a rapid 5-*exo*-trig cyclization of an alkyl (or a vinyl) radical upon phenyl sulfonyl radical addition, the whole process being terminated by the azidation step. The desired products are obtained with excellent yields (**40** and **41** respectively, Figure 17), although with low diastereoselectivity.

The group of Landais investigated distinct pathways for the cyclization of silylheptadienes **41** (Figure 18).⁶⁹ In particular, a sulfonyl radical triggers regioselective addition and subsequent 5-*exo*-trig cyclization of these dienes (at low temperatures up to 9 to 1 regioselectivity at the allylsilane terminus is achieved in **42**) while a thiyl-mediated reaction features a different outcome, as it is terminated by homolytic substitution at sulfur to yield a thiabicyclic product **43**.

Figure 17 Azidosulfonylation of dienes and enynes coupled with 5-*exo*-trig cyclization.

Figure 18 Different radical-mediated cyclizations of silylheptadienes.

A brief example of the relevance of thiophenol as a mediator in radical cascades is presented hereafter, while its role is presented more in detail in the section of this encyclopedia dedicated to sulfur-centered radicals (see **Main-Group Elements in Radical Chemistry**). The group of Renaud investigated various cascade reactions mediated by thiophenol. This reactivity has been applied for instance to *N*-homopropargylic piperidinones (45, Figure 19), which cyclize smoothly after

addition of a thiyl radical, leading to compound 46 through a sequential 1,5-hydrogen transfer, 5-*exo*-trig cyclization, and final reduction. Products are obtained in good yields and diastereoselectivities, and could be easily transformed to the corresponding *exo*-methylene derivatives 47 by oxidation to the related sulfoxides followed by thermal elimination.⁷⁰

Parsons reported an efficient approach to organophosphorus derivatives belonging to the

Figure 19 Thiophenol-mediated 1,5-hydrogen transfer followed by cyclization.

Figure 20 Sequential addition/cyclization of a P-centered radical on diallylether.

class of phosphonothioates, phosphinothioates, and phosphane sulfides.⁷¹ He showed that a phosphinothioate, such as **48**, which features a relatively weak P–H bond, can easily react with diallylether to deliver tetrahydrofurans **49** in excellent yields via a 5-*exo*-trig cyclization (Figure 20).

Formation of a P(V)-centered radical from an alkyne thiophosphonates could be exploited in several bond-forming processes. For instance, *S*-pentynyl thiophosphine oxides or dithiophosphonates (**50**, Figure 21) smoothly underwent cycloisomerization using thiophenol as a radical promoter to yields products **51** in good yield. Interestingly, the reactivity of the P-centered radical could be steered to an intermolecular fashion in the presence of an excess of olefin, leading to the adduct **52**.⁷²

The group of Landais reported the synthesis of fused piperidinones through a radical cascade and subsequent intramolecular lactamization.^{73,74} The reaction of an allylsilane bearing an oxime function (**53**, Figure 22) with a suitable α -halo ester affords the desired bicyclic products in good yield and with high diastereoselectivity. The radical from an α -iodoacetate adds to the less substituted

position of the alkene function of **53**, to generate a nucleophilic radical **54** which cyclizes through a 5-*exo*-trig process, providing a nitrogen-centered radical. At this stage, depending on the substitution of the oxime, two distinct pathways can occur. Employing carbon unsubstituted oximes, **55** can react with triethylborane to yield the amine–borane complex **56** which undergo a final lactamization via a polar crossover process, giving rise to the acyclic product **57**.

Grainger successfully employed the generation of a carbamoyl(aminoacyl) radical from the corresponding dithiocarbamate precursor (**58**, Figure 23) as a key step in the formal synthesis of (–)-aphanorphine to construct the azabicyclic core **61**.⁷⁵ Photomediated cleavage of the carbon–sulfur bond in **58** generates the carbamoyl radical **59**, which stereoselectively cyclizes through a 5-*exo*-trig process to give the carbon-centered radical **60**, which is eventually trapped by the dithiocarbamate **58** via a group transfer reaction.

Miyabe and Takemoto recently reported their progress in the field of enantioselective radical cyclizations through a Lewis acid tether approach (see **Stereoselective Radical Reactions**).^{76,77}

Figure 21 Selective reaction of conjugated acyclic trienes to polycyclic systems.

Figure 22 Different outcomes of the radical cascades between an haloester and an allylsilyloxime.

Figure 23 Photomediated radical reaction of a dithiocarbamate featuring sequential cyclization/group transfer.

Stereocontrol in this radical cascade was achieved through crucial coordination of a zinc chiral complex during the key cyclization step (intermediate **62**). This cascade features an initial radical addition onto the double bond of an oxime ether and the subsequent stereoselective ring closure directed by the chiral bis-oxazoline ligand on the zinc

metal center. The resulting radical could then be quenched by a halide to propagate the sequence. This approach was applied to the synthesis of various lactams such as **63** (Figure 24).

2.2.2 Sequences Involving Formation of Six-Membered Rings

The group of Zard reported the formal synthesis of mersicarpine through an intermolecular radical addition/cyclization cascade.⁷⁸ Activation of an indole xanthate (such as **64**, Figure 25) by lauroyl peroxide allows the addition of the resulting carbon-centered radical on a terminal olefin, delivering the intermediate **65**, which then undergoes 6-*exo*-trig cyclization to the indole ring **66**. This radical led to the product **67**, along with **68**, obtained either through disproportionation or by hydrogen transfer to the peroxide. The authors reported that the presence of an electron-withdrawing carboxylate substituent at the 3-position of the heterocycle is crucial for the process, suggesting that the reversibility of the radical addition onto the indole could be overcome by proper stabilization of the intermediate **66**.

Figure 24 Enantioselective radical cyclizations triggered by chiral zinc complexes.

Figure 25 Access to polycyclic indoles by radical addition/cyclization.

Alabugin and coworkers reported an elegant radical cascade that involves three consecutive ring closures.⁷⁹ Initial addition of a tributyltin radical on the central triple bond of a terminally substituted tris(*o*-aryleneethynylene) (**69**, Figure 26) allows to obtain the desired products **70** and **71** in good yield after acidic destannylation. However, as the success of the process depends on the regioselectivity of the initial radical addition, the scope of the sequence is limited to substrates bearing terminal phenyl, *p*-tolyl (**70**) or trimethylsilyl (**71**) groups. A complex mechanism is at work in this cascade that involves,

besides cyclizations, hydrogen atom abstraction from a terminal TMS group in the latter case.

The group of Bennasar proposed a radical route to the quinine-based natural product calothrixin B.⁸⁰ As a part of their studies on the generation of 2-indolylacyl radicals from the corresponding phenyl selenoesters, the authors synthesized the radical precursor **72** (Figure 27). They propose that the initial abstraction of the selenoester group by a silyl radical delivers the acyl radical **73**, which undergoes a regioselective cyclization on the quinoline ring to afford radical **74**. Oxidation of **74**

Figure 26 Selective reaction of conjugated acyclic triynes to polycyclic systems.

Figure 27 A radical cascade as key step in the formal total synthesis of calothrixin B.

by AIBN-induced hydrogen abstraction, followed by H-abstraction at the C-ring benzylic position generates radical **75**, which quenches the radical derived from AIBN decomposition. However, it is rather surprising that a radical/radical recombination step should be so selective. Other mechanisms are probably operative.

2.2.3 Miscellaneous

The group of Ryu has been active in the field of radical cascades including radical carbonylation steps. They reported the synthesis of methylene-2-piperidinones by an efficient carbonylation of an alkynyl imine in the presence of tributyltin hydride and AIBN (Figure 28; product **76** is shown before acid destannylation).⁸¹ When the substituent on the nitrogen is a suitable leaving

group, such as an α -styryl one, 2-methylenelactams could be selectively obtained through the same approach.⁸² The authors expanded the synthetic applications of this method to α,β -unsaturated compounds bearing a terminal triple bond and using an alkyl thiol as mediator. When employing substituted acrylates, a 5-*exo* cyclization occurred and led to the formation of compound **77**.⁸³ When the ester group of the reagent is replaced by a nitrile function, the same reactivity can be observed with trimethylsilylhydride as mediator instead of the thiol. Further developments were accompanied by theoretical studies on the reaction mechanism^{84,85} and allowed the group to achieve the tin-radical-mediated synthesis of 3-substituted cyclohexanones **78**. Interestingly, in the presence of allyltributyltin a four-component cascade delivers product **79**, which features a quaternary carbon at the 3 position of the cyclic ketone.⁸⁶ The

Figure 28 Radical cascades involving carbonylation of a carbon-centered radical.

Figure 29 Radical carboazidation in the total synthesis of lepadiformine.

Figure 30 Three-component intermolecular cascade involving B-cyclohexylcatecholborane.

three-component coupling of a substituted allyl sulfone, carbon monoxide, and a phenylsulfonyl oxime similarly delivers a substituted acylated oxime **80**, together with allyl phenyl sulfone as the coproduct.⁸⁷

2.3 Radical Cascades Involving Intermolecular Steps Only

Renaud proposed a total synthesis of lepadiformine in which one of the key step is a carboazidation of a substituted methylenecyclohexane as shown in Figure 29.^{88,89} Hexabutylditin was used to generate an α -carboethoxy radical, which adds at the *exo*-methylene position of the olefin. The resulting radical is quenched by azidation from pyridinesulfonylazide to give **81** in good yield.

The same group proposed an interesting three-component radical-mediated sequence using B-alkylcatecholboranes (Figure 30).⁹⁰ The B-alkylated

adduct derived from cyclohexene and placed in the presence of oxygen generates efficiently a nucleophilic carbon-centered cyclohexyl radical, which added smoothly to an electrophilic double bond. Termination was achieved by allylation from a substituted allylsulfone, yielding the desired product **82**.

3 CASCADE REACTIONS INVOLVING NON-CHAIN REDOX PROCESSES

3.1 Cascade Reactions Promoted by Titanium Complexes

Titanium(III) chloride and related complexes constitute remarkable single-electron reductive reagents, widely used in organic synthesis for promoting radical reactions (see **Epoxides in Titanocene-Mediated and -Catalyzed Radical Reactions**). As

Figure 31 Carbodiazenylation of alkenes from aryldiazonium salts.

Figure 32 Radical version of the Strecker synthesis of α -aminoamides.

reported by Heinrich, carbodiazenylation of non-activated olefins can be accomplished with aryl-diazonium salts in the presence of TiCl_3 .⁹¹ The reduction of the diazonium salt by Ti(III) generates an aryl diazenyl radical. After nitrogen extrusion, the aryl radical liberated can add on to the olefin to form an intermediate alkyl radical, which then reacts with a second equivalent of diazonium salt. The resulting aminyl radical cation was finally reduced to the azo compound (Figure 31). This process allowed achieving the carbodiazenylation of nonactivated alkenes through an easy way. Neither dry solvents nor an inert atmosphere were needed to reach good yields. The carbodiazenylation was then extended to aliphatic derivatives through initial radical iodine atom transfer reactions of iodoacetonitrile and iodoacetate with the olefin.⁹²

A radical version of the Strecker synthesis of α -aminoamides in aqueous medium was proposed by Porta. This three-component reaction between formamide, an amine, and an aldehyde mediated by the $\text{TiCl}_3/\text{H}_2\text{O}_2$ system proceeded efficiently to

afford α -aminoamides (Figure 32).⁹³ The proposed mechanism first involves reduction of H_2O_2 by Ti(III) to the hydroxyl radical, followed by hydrogen atom abstraction from formamide. The resulting nucleophilic carbamoyl radical adds to the imine, generated *in situ* by condensation between the aldehyde and the amine with assistance of Ti(IV) salts, and liberates the aminium radical. Then, a final reduction of this intermediate by Ti(III) provides the α -aminoamide. A wide range of α -aminoamides was synthesized with moderate to good yields starting from cheap and commercially available substrates. This methodology was then extended to the aminomethylation of ethers⁹⁴ and the hydroxymethylation of imines⁹⁵ leading, respectively, to 1,2-amino ethers and 1,2-amino alcohols. As reported recently, addition to ketimines allowed the formation of quaternary α -aminoamides.⁹⁶

Titanocene(II) chloride (Cp_2TiCl) is a common and efficient reductive reagent for radical ring opening of epoxides, which can trigger radical polyene cyclization cascades.⁹⁷ Fernandez-Mateos disclosed

Figure 33 Quadruple radical cyclization terminated by a 4-*exo* process onto nitrile.

Figure 34 Titanocene-catalyzed epoxypolyene cyclization.

interesting examples of radical cascade cyclizations of unsaturated epoxynitriles with noticeable yields and diastereoselectivities.⁹⁸ Homolytic cleavage of epoxide **83** complexed with Cp_2TiCl gave the corresponding β -alkoxy radical, which underwent three successive 6-*endo*-trig cyclizations followed by a 4-*exo*-dig cyclization onto the nitrile group as the termination step. After hydrolysis, the tetracyclic ketone **84** was isolated in 50% yield as a unique diastereoisomer (Figure 33).

Gansäuer *et al.* applied their new catalytic system $\text{Cp}_2\text{TiCl}/2,4,6$ -collidine to the radical epoxypolyene cyclization of the epoxyfarnesyl derivative **85** for the formal synthesis of puerhedione and its 8-epimer. The key steps feature two 6-*endo*-trig cyclizations and subsequent β -hydride elimination of an intermediate Ti derivative to yield the bicyclic alcohol **86** as a common building block for marine natural products and other derivatives (Figure 34).⁹⁹

Barrero *et al.* reported some results on cascade cyclizations of epoxypolyenes catalyzed by Cp_2TiCl for the synthesis of 6-5, 6-6, and 6-7 bicyclic frameworks. The size of the second ring can be tuned by changing the substitution pattern and modulating the electronic nature of the double bond involved in the last cyclization step.¹⁰⁰ Finally, Kobayashi realized the synthesis of AB ring moiety of fomitelic acids via a titanium-mediated radical cyclization of epoxypolyene **87**.¹⁰¹ This reaction was completely stereocontrolled, leading to the tricycle **88** in moderate yields (Figure 35).

Figure 35 Synthesis of the AB ring moiety of fomitelic acids.

3.2 Cascade Reactions Promoted by Manganese Complexes

On the basis of Snider's chemistry, manganese(III) acetate proved a powerful oxidative reagent that can be used to perform radical cascade reactions (see **Manganese(III) Acetate, CAN, and Fe(III) Salts in Oxidative Radical Chemistry**). In 2006, Chen disclosed an efficient synthesis of various polycyclic core skeletons of natural products such as ageliferin or massadine, involving Mn(III)-mediated oxidative heterobicyclizations leading to the formation of two C–C bonds and three stereogenic centers.¹⁰² The treatment of allylic β -imidazolinonyl- β -ketoesters with $\text{Mn}(\text{OAc})_3$ produced lactone tricyclic compounds by either a 5-*exo*-trig/6-*endo*-trig or a 5-*exo*-trig/5-*exo*-trig cascade radical cyclization. The regioselectivity depends of the substitution of the imidazolinonyl ring. For instance, the allylic β -imidazolinonyl- β -ketoester **89** is first oxidized by the Mn(III) salt to form a radical species, which then cyclizes cleanly into the tricycle **90**. The resulting radical was oxidized by another equivalent of Mn(III) and a proton was eliminated (Figure 36). Most of the transformations were performed with good yields, regioselectivities, and diastereoselectivities.

Figure 36 Mn(III)-promoted 5-*exo*/6-*endo* radical cyclization reactions.

Figure 37 Radical cascade of polyene **91** terminating onto a pyridine ring.

González reported a new approach to the synthesis of spongidines based on the oxidative radical cyclization promoted by $\text{Mn}(\text{OAc})_3$ of an unsaturated β -ketoester containing a pyridine ring as radical trap. The reaction of polyene **91** gave

an isomeric structure of natural spongidines in moderate yield but with an excellent selectivity (Figure 37).¹⁰³

El Kaim studied the functionalization of Ugi adducts, resulting from a four or five component

Figure 38 Radical cascade from an Ugi adduct and ethyl malonate induced by $\text{Mn}(\text{OAc})_3$.

Figure 39 Mn(III)-catalyzed synthesis of pyrrole from ethyl acetoacetate and styrene azide.

Figure 40 Atom transfer carbonylation of a secondary alkyl iodide.

reaction, through a Mn(III)-based radical cascade of malonates or β -ketoesters involving both inter- and intramolecular steps. In the following example, the malonyl radical generated by oxidation of diethyl malonate with $\text{Mn}(\text{OAc})_3$ adds onto olefin **92** and the resulting alkyl radical operates a 1,4-aryl transfer reaction. After oxidative cleavage and subsequent 5-*exo*-trig cyclization, indane **93** was isolated in 59% yield. It is noteworthy that when the second oxidative cyclization cannot occur, the corresponding δ -amidomalonate is obtained (Figure 38).¹⁰⁴

A new method for the synthesis of substituted pyrroles was proposed by Chiba and Narasaka and involved the Mn(III)-mediated cascade radical reaction of 1,3-dicarbonyl compounds and vinyl azides.¹⁰⁵ Several examples were performed by changing either the vinyl azide or the 1,3-dicarbonyl

compound, for example, β -ketoester or diketone (Figure 39). Details about this process are reported in **Main-Group Elements in Radical Chemistry**.

Manganese can also accelerate radical reactions such as the atom transfer carbonylation of alkyl iodides. Ryu showed that $\text{Mn}_2(\text{CO})_{10}$ is an effective catalyst for the transformation of primary, secondary, and tertiary alkyl iodides into carboxylic acid esters. Dimanganese decacarbonyl acts as a radical initiator and accelerates the carbonylation under irradiation (Figure 40).¹⁰⁶

Studer reported the formation of aryl radicals by the treatment of arylboronic acids with $\text{Mn}(\text{OAc})_3$ and their subsequent addition to alkenes. The resulting alkyl radical can either be trapped by oxygen under aerobic conditions or sequentially react with a second equivalent of alkene and then cyclize

Figure 41 Radical cascade reactions with arylboronic acids and alkenes under oxidative conditions.

Figure 42 Fe(I)-catalyzed ring expansion of styrene oxide with styrene.

Figure 43 Intramolecular Fe(I)-catalyzed ring expansion.

through homolytic aromatic substitution to give arylhydroxylation products (**94**) and tetrahydronaphthalene derivatives (**95**), respectively (Figure 41).¹⁰⁷

3.3 Cascade Reactions Promoted by Iron Complexes

Hilt showed that low-valent iron(I) species, generated by reduction of iron(II) complexes with zinc powder, can catalyze inter- and intramolecular ring expansion reactions of epoxides in the presence of alkene moieties and furnished substituted tetrahydrofurans. Reduction of epoxystyrene by single-electron transfer from the iron(I) species provokes its ring opening and liberates the β -alkoxy iron(II) radical **96**, which can add to the alkene. A back electron transfer from the alkyl radical to the iron complex generates a stabilized

carbocation **97**, which subsequently cyclizes to form the tetrahydrofuran ring **98** (Figure 42).¹⁰⁸ Similarly, ring expansion of epoxylkene **99** gives rise to the corresponding bicyclic tetrahydrofuran **100** (Figure 43).¹⁰⁹ Noticeable improvements in diastereoselectivities from the original iron system were realized when using a salen-type ligand in the place of a diphosphine. An extension of this reaction to the synthesis of hexahydrocyclopenta[*c*]furans was also proposed.¹¹⁰

Another interesting aspect of iron chemistry is the reduction of diazonium salts reported by Heinrich and its participation in cascade reactions. Upon treatment with FeSO_4 , aryl diazonium salts generate aryl radicals which can add onto activated as well as nonactivated olefins. Then, the resulting alkyl radical can be trapped by a nitroxyl radical such as TEMPO (Figure 44).¹¹¹ The authors observed that the starting diazonium can be used itself as a radical scavenger when nonactivated alkenes are

Figure 44 Intermolecular radical carboaminohydroxylation of olefins.

Figure 45 Intermolecular radical carbodiazenylation of olefins.

Figure 46 Iron(II)-mediated three-component carbodiazenylation reaction.

used. On the basis of this observation, an efficient radical carbodiazenylation process was developed (Figure 45).¹¹² In a recent work, Henrich envisaged combining the reduction of hydroperoxide **101** by

FeSO₄, which generates an ethyl acetate radical, with carbodiazenylation of nonactivated alkenes (Figure 46).¹¹³

Examples of cascade reactions involving iron(III)-mediated oxidation processes have also been reported. For instance, MacMillan achieved enantioselective cascade (4 + 2) cycloadditions between aldehydes with a pendant aromatic system and styrenes through asymmetric semi-occupied molecular orbital (SOMO) catalysis (Figure 47). Oxidation of the enamine, derived from the condensation of an aldehyde with a chiral imidazolidinone, delivers a radical cation which then participates in an olefin addition/radical oxidation/Friedel–Crafts sequence and provides enantioenriched substituted cyclohexyl rings. The good results obtained in terms of yields, diastereo- and enantioselectivities

Figure 47 Cascade reactions of aldehydes and olefins using enantioselective SOMO-catalysis.

Figure 48 Radical reaction of methyl carbazate and α -methylstyrene in the presence of Fe(Pc).

Figure 49 Atom transfer radical process by reduction of α -dichloro- β -ketoesters.

makes this process a powerful tool in organic synthesis.¹¹⁴

Taniguchi examined the intermolecular addition of alkoxy carbonyl radicals, generated by oxidation of the corresponding carbazates (**102**) by iron phthalocyanine, to alkenes in the presence of air. Thus, the reaction of various carbazates and terminal/gem-disubstituted alkenes afforded β -hydroxyesters in moderate to good yields (Figure 48).¹¹⁵

3.4 Cascade Reactions Promoted by Copper Complexes

Recently, Yang reported the single electron transfer reduction of α -dichloro- β -ketoesters (**103**)

catalyzed by copper(I) complexes (Figure 49).¹¹⁶ A chlorine atom transfer occurred in this radical cascade process involving polycyclizations. 6-*Endo*/5-*exo* and 6-*endo*/6-*exo* sequences have been done with moderate to good yields to afford bicyclic products (**104**). In order to reduce the Cu(II)/Cu(I) redox potential, ligands like bipyridine or bis(oxazoline) have to be used and the reduction of C–Cl bond allowed. The same procedure has also been applied to more simple systems to form cyclopentanone and cyclohexanone derivatives.

A copper-catalyzed cascade radical cyclization route has been proposed for the synthesis of benzospiro-indolizidinepyrrolidinones derivatives (Figure 50).¹¹⁷ Following an atom transfer radical process, the indole derivative **105** afforded the tetracyclic products **106** in moderate yields. The reduction of one C–Cl bond of the trichloroacetamide moiety generated a 1-(carbamoyl)dichloromethyl radical that initiated a 5-*exo*/6-*endo* cyclization sequence with a total diastereoselectivity.

MacMillan developed an enantioselective polyene cyclization mediated by copper(II) salts involving the organocatalysis concept also (Figure 51).¹¹⁸ An aldehyde function reacted with a chiral amine to generate the corresponding enamine derivative that was oxidized by copper(II) triflate according to

Figure 50 Copper-catalyzed cascade radical cyclization accessing spiro compounds.

Figure 51 Enantioselective polyene cyclization involving organo-SOMO catalysis.

Figure 52 Three-component radical-polar crossover reaction.

a single electron transfer process. The resulting radical cation started the cascade reaction leading to the formation of polycyclic compounds (**107**) in good yields and enantioselectivities. Tri- to hexacyclic steroid analogs **108** and **109** have been obtained by this efficient transformation.

3.5 Cascade Reactions Promoted by Zinc Complexes

Bertrand reported the use of dialkylzinc in the presence of oxygen as chain-transfer reagent, which constitutes an alternative to borane reagents.

This reactivity was highlighted by the addition of C-centered radicals onto imines and enones.^{119,120} The same group published a one-pot, three-component, radical-polar crossover reaction (Figure 52).¹²¹ Under air atmosphere, the diethylzinc allowed the formation of an ethyl radical that can add onto Michael acceptor or generate the *tert*-butyl radical by iodine abstraction. Then, zinc enolate was immediately formed by homolytic substitution on the diethylzinc and reacted with benzaldehyde with moderate diastereoselectivities.

More recently, Chemla described a related radical-polar crossover cascade reaction with organozinc and mixed organocopper/organozinc

Figure 53 Radical-polar crossover cascade reaction initiated by organozinc reagents.

reagents. This sequence involved a radical Michael addition followed by a 5-*exo*-trig cyclization to afford pyrrolidine derivatives.¹²² This was extended by the same group to a stereoselective zinc atom radical transfer involving alkynes (Figure 53).¹²³ β -(Propargyloxy) enoates reacted with dialkylzinc reagents in the presence of oxygen. The so-formed alkyl radical added onto the acrylate moiety followed by a 5-*exo*-dig cyclization. The resulting vinyl radical underwent a homolytic substitution on alkylzinc to afford a vinyl zinc intermediate that reacted with the electrophilic iodine.

Dimethylzinc-mediated radical-anionic cascade have been proposed by Bertrand and Feray for the stereoselective synthesis of oxygenated five-membered ring heterocycles (Figure 54).¹²⁴ Depending on the additive, synthesis of lactone dihydrofuran, and lactol derivatives can be achieved in good to high yields. In the case of lactones, a diastereoselective acyl group transfer has been highlighted proceeding through a zinc enolate addition onto one ester function.

3.6 Cascade Reactions Promoted by Silver Complexes

In the context of single-electron transfer oxidation, Narasaka reported the generation of β -keto radicals from cyclopropanols by using silver(I) salts and ammonium persulfate as co-oxidant (Figure 55).¹²⁵ This transformation has been previously proposed by the same group with $\text{Mn}(\text{pic})_3$. The oxidant is supposed to be an $\text{Ag}(\text{II})$ complex that would be formed by the oxidation of $\text{Ag}(\text{I})$ with persulfate. Cyclopropanol derivatives were oxidized to the corresponding alkoxy radical that underwent a β -scission to afford the β -keto radical. This intermediate reacted with the electron-poor acrylonitrile followed by the addition of the resulting

Figure 54 Dimethylzinc-mediated radical-anionic cascade reaction.

Figure 55 Multicomponent reaction initiated by the oxidation of cyclopropanol derivatives.

Figure 56 Oxidation of β -nitroamide or ether anions by silver salt.

electron-deficient radical onto the electron-rich enol ether. The same group applied this process in the total synthesis of (–)-sordarin.¹²⁶

Kamimura's group investigated the ability of Ag_2O to oxidize β -nitroamide or ether anions in a radical-anion cascade reaction and obtain bicyclic nitrocyclopropane derivatives (**110**) (Figure 56).¹²⁷ Deprotonation by 1,8-diazabicyclo[5.4.0]undec-7-ene (DBU) at the α position of the nitro group and the subsequent single electron transfer (SET) generated the α -nitro radical, which underwent 5-*exo*-trig cyclization. The resulting primary radical was able to react with I_2 to afford the corresponding primary iodide. Finally, the cyclopropyl ring was obtained by intramolecular nucleophilic substitution with good stereoselectivity. 6-*exo*-trig Cyclizations were also investigated to yield 6,3-bicyclic compounds (**110**).

3.7 Cascade Reactions Promoted by Cerium Complexes

Cerium ammonium nitrate (CAN) has been widely used as a single-electron oxidant in many cascade organic reactions (see **Manganese(III) Acetate, CAN, and Fe(III) Salts in Oxidative Radical Chemistry**).¹²⁸ Its low toxicity, ease of experimental setup, and good solubility in several organic

solvents have shown its high utility in organic synthesis. A well-known activity of CAN is its ability to oxidize 1,3-dicarbonyl compounds into their radicals, which can react with substituted alkenes to form cyclic adducts. Different carbon skeletons can be formed with different alkenes. For example, Nair has reported the reaction between 1,3-dicarbonyl compounds and diphenylmethylenecyclopropane to form 5-oxaspiro[2.4]hept-6-ene derivatives (**111**) (Figure 57a).¹²⁹ whereas Meréndez has recently reported a CAN-promoted cyclization reaction between 1,3-cyclohexadiones and diaryl α,β -unsaturated ketones to furnish 2,3,6,7-tetrahydrobenzofuran compounds (**112**) (Figure 57b).¹³⁰ In both cases, the mechanism follows a radical addition to the alkene followed by cationic cyclization with one of the carbonyl groups of the dione.¹³¹

A similar pathway was also observed in the oxidation of styrene oxides allowing intramolecular cyclization with the styrene moiety in compound **113** (Figure 58a). The intermolecular trap of the formed benzyl cation with acetonitrile results in the formation of substituted piperidine **114** in good yields.¹³² On the other hand, *N*-vinyl amides can also be oxidized by CAN in the presence of diaryl imines to afford 1,2,3,4-tetrahydroquinolines **115** in high yields (Figure 58b).¹³³

Figure 57 Cascade reactions of 1,3-dicarbonyls mediated by Ce(IV).

Figure 58 Oxidation of styrene oxides and *N*-vinyl amides by CAN.

3.8 Cascade Reactions Promoted by Samarium Complexes

Samarium diiodide became popular as a reducing agent in organic synthesis since its discovery by Kagan (see **Organic Synthesis Using Samarium Diiodide**). This one-electron-transfer reagent has been largely used thanks to the mild conditions it requires and its generally good chemoselectivity. Moreover, it is known to undergo either radical or ionic processes. Procter reported “radical then aldol” cyclization cascades from dialdehyde substrates (**116**), leading to tricyclic products (**117**) (Figure 59).¹³⁴ The reduction of one aldehyde function afforded the corresponding ketyl radical anion (**118**), which underwent an anti-selective 5-*exo*-trig radical cyclization onto the activated olefin with the formation of samarium enolates via an anti-selective pathway. By chelation to samarium(III), a diastereoselective aldol cyclization involving a six-membered transition structure **119** occurred and the final tricyclic compound **117** was obtained. Precoordination of samarium to the ester would favor the reduction of the nearer aldehyde selectively, thus explaining the difference in reactivity between the two aldehyde groups. This methodology has been applied by the same group to an original approach to pleuromutilin.¹³⁵

Polycyclic *N*-heterocycles can also be synthesized from cyanamides by intramolecular cascades

promoted by samarium diiodide (Figure 60).¹³⁶ The reduction of aryl iodide **120** led to the formation of aryl radical **121** which cyclized onto the nitrile group in a 6-*exo*-dig manner. The so-formed iminyl radical **122** underwent a 6-*endo*-trig cyclization followed by rearomatization and led to compound **123**. This transformation has been applied to the total synthesis of natural products or analogs.

Samarium diiodide proved to be very effective in cascade reactions. Thus, its applications in total synthesis are useful. In this field, Reissig reported a short formal total synthesis of strychnine by an SmI₂-induced cascade reaction (Figure 61).¹³⁷ In this key step, two cycles and three stereogenic centers were built with a high stereoselectivity and good yield. This forms the shortest route yet reported to racemic strychnine.

Procter reported the transformation of lactones bearing two alkenes or alkyne/alkene under reductive conditions.¹³⁸ An SmI₂/H₂O mixture allowed the formation of decorated azulenes in high yields and good diastereoselectivities (Figure 62). This reaction proceeds through unusual radical anion intermediates. The diastereoselectivities were rationalized by calculations. The same group reported a stereoselective cyclization cascade mediated by SmI₂/H₂O, which was applied in a study toward the synthesis of stolonidiol.¹³⁹

3.9 Visible-Light Photocatalysis Promoted Cascade Reactions

Owing to its high efficiency and convenience, photocatalysis using visible light has become a promising, environmentally benign tool for organic synthesis (see **Synthetic Radical Photochemistry**). On the basis of the seminal work of Kellogg, a revival of this chemistry came about.¹⁴⁰ Recently, Stephenson has shown that carbon radicals formed by reductive cleavage of activated C–Br bonds in 2-bromomalonate esters can undergo efficient and diastereoselective 5-*exo*-trig/6-*exo*-trig (a)¹⁴¹ or 5-*exo*-trig/5-*exo*-dig (b)¹⁴² cascade radical cyclizations (Figure 63). This process is initiated by the oxidative quenching of the excited state of a metal complex such as tris(bipyridine)ruthenium(II) ($\text{Ru}(\text{bpy})_3^{2+}$), a commonly used photoredox catalyst, by SET from an electron donor (e.g., amine). Consequently, the metal catalyst becomes a strong reducing agent in its reduced form (e.g., $\text{Ru}(\text{bpy})_3^+$), which undergoes a second SET to

Figure 63 Radical polycyclizations initiated by reductive cleavage of activated C–Br bonds.

the organic substrate (bromide), and thus starts the catalytic cycle and regenerates the catalyst.

Yoon has also performed visible light photoredox catalysis in the [2 + 2] cycloadditions of enones.¹⁴³ It was shown that using a mixture of $\text{Ru}(\text{bpy})_3\text{Cl}_2$, *i*-Pr₂NEt and LiBF₄, aryl enones can be reduced to radical anions, which add to other enones and subsequently undergo 4-*exo*-trig cyclization to furnish cyclobutane adducts with excellent diastereoselectivity (Figure 64). Interestingly, the scope of this reaction was expanded to the toward the intramolecular cyclization of bis(enones). At least one aryl enone in a bis(enone) is required to facilitate the reduction (SET) process and, as a result, to undergo an intramolecular [2 + 2] cycloaddition to afford 4,5-membered fused bicyclic compounds (Figure 65a).^{144–146} An equivalent pathway was also observed when similar conditions were applied for the reduction of aryl cyclopropyl ketones.¹⁴⁷ In this case, 5,5-membered fused bicyclic compounds were formed in high stereoselectivity and good yields but needed the intervention of an additional Lewis acid (Figure 65b).

It is noteworthy that in all of the above examples, a sufficiently electron-poor substrate is required for a smooth reduction step. In contrast, Yoon have also performed the oxidative photocatalysis of electron-rich styrenes.¹⁴⁸ Hence, such reaction is initiated through the oxidative quenching of the

Figure 64 Intermolecular photoredox-catalyzed [2 + 2] cycloaddition.

Figure 65 Intramolecular photoredox-catalyzed cycloadditions.

metal catalyst excited state $\text{Ru}(\text{bpy})_3^{2+*}$ by a good electron acceptor (e.g., methyl viologen MV^{2+}) to generate $\text{Ru}(\text{bpy})_3^{3+}$. Then, the electron-rich styryl moiety is oxidized into the radical cation, which can be involved in a cascade reaction. The formation

of 4,5-membered fused bicyclic compounds from the photocatalyzed [2 + 2] cycloaddition of aryl bis(styrenes) was demonstrated (Figure 66). This clearly shows how sensitive the reaction is to the nature and position of substituents on the styrene

Figure 66 Intramolecular photoredox-catalyzed [2 + 2] cycloaddition.

ring and that the presence of an electron-donating group (e.g., MeO) is necessary for the oxidation/cycloaddition to occur.

4 CONCLUSIONS AND PERSPECTIVES

Radical cascades have demonstrated that they are particularly powerful tools to access complex scaffolds in one step starting from simple precursors. This efficiency has been illustrated by their involvement in numerous straightforward syntheses of natural compounds. The use of tin and silicon mediators has allowed the development of sequences featuring a high increase in molecular complexity and successfully involving a wide variety of radical partners. In order to avoid the toxicity and contamination issues inherent to the use of tin, the design of tin-free cascade reactions has been an area of intense research efforts over the last decade. The use of stoichiometric amounts of metal-based reagents such as titanium(III), samarium(II) species, and many others has proven its relevancy in this field. Excitingly, efficient cascades triggered by metal reagents used in catalytic amounts are now emerging, and open a new bunch of perspectives in term of sustainability, development of enantioselective processes, and diversity of mechanisms. One can certainly anticipate a lot of breakthroughs in this area over the coming years.

Main-Group Elements in Radical Chemistry

Alexandre Baralle, Abdulkader Baroudi, Marion Daniel, Louis Fensterbank, Jean-Philippe Goddard, Emmanuel Lacôte, Marie-Hélène Larraufie, Giovanni Maestri, Max Malacria and Cyril Ollivier

UPMC Univ Paris 06, Sorbonne Universités, Institut Parisien de Chimie Moléculaire (UMR CNRS 7201), Paris, France

1 INTRODUCTION

In this article, we focus on aspects of free-radical chemistry that involve main-group elements. This can mean synthetic chemistry of heteroatom-centered radicals or reactions onto heteroatom-containing moieties. Main-group radical chemistry is a very large domain, which has been separated into several reviews of this encyclopedia. This article is dedicated to nitrogen-, oxygen-, phosphorus-, sulfur-, and selenium-based heterochemistry.

2 NITROGEN-CENTERED RADICALS

N-Centered radicals can be easily obtained by homolytic cleavage of relatively weak bonds, for example, N–N, N–S, N–O, and N–halogen bonds, and also strong N–H and N–C bonds starting from readily available nitrogen-based chemical functions, for instance, azides, or more elaborated precursors. Aminyl, iminyl, and amidyl radicals can be formed to take part in radical transformations generating heterocyclic structures found in natural products. This is covered through-

out this article, which is meant as an update to a book chapter and a tutorial review published in 2001 and 2008, respectively, by Stella¹ and Zard.²

2.1 N-Centered Radicals by Homolytic N–N Bond Cleavage

2.1.1 From Azide Compounds

Although organic azides are synthetically useful intermediates, their behavior toward radical species had been overlooked (see **Unusual Radical Acceptors**). Yet, radical reactions of azides have gained renewed interest recently. This chemistry has been thoroughly reviewed by Spagnolo.³ Carbon or heteroatom radicals can add at the α or γ position of the azido moiety to give 1,3- or 3,3-triazenyl radicals **1** and **2**. With both aliphatic and aromatic azides, the latter fragments by loss of N₂ to form an aminyl radical, whereas with sulfonyl azides the 1,3-triazenyl radical intermediate releases the corresponding alkyl azide and a sulfonyl radical by β -elimination (Figure 1). This aspect is addressed further in Section 5.

Figure 1 Homolytic addition to azides and generation of aminyl radicals.

Figure 2 Generation of *N*-stannylaminyl radicals and intramolecular addition onto enol ethers.

Intermolecular addition of stannyl radicals to alkyl azides provides transient stannylaminyl radicals which can cyclize onto C=C double bonds to form heterocyclic rings. Recently, Sammis reported diastereoselective cyclizations of aminyl radicals **5**, generated from azides **3**, onto electron-rich silyl enol ethers for the preparation of polysubstituted pyrrolidines **4**. In this transformation, the nature of the substituent in allylic position and the configuration of the vinyl ether turned out to be critical for controlling the diastereoselectivity (Figure 2).^{4,5}

Stannylaminyl radicals can add intramolecularly to electrophilic cyano groups to form aminoimidyl radicals, which can undergo further cyclizations onto suitably positioned alkenes and aromatic rings. Leardini and Spagnolo showed that radical domino

Figure 3 Intramolecular addition of *N*-stannylaminyl radicals onto nitriles or cyanamides.

reactions involving unsaturated azidoethyl- and azidopropylmalononitriles proceed in good yields and generate a variety of pyrro- and pyrrolopyridine derivatives (Figure 3, equation a).⁶ A similar strategy was adopted for the first radical preparation of bi- and tricyclic guanidines using cyanamides as relay partners. In this case, the final step of the cascade is achieved by a radical aromatic substitution of the iminyl-type radical intermediate (Figure 3, equation b).⁷

Stannylaminyl radicals also undergo rapid intramolecular 3-*exo*-trig cyclizations to the ketone carbonyl of β -keto esters. The resulting alkoxy radicals can β -fragment to generate lactams. For example, cyclic α -azido β -keto esters **6** treated in the presence of Bu_3SnH /azobisisobutyronitrile (AIBN) provide the corresponding ring-expanded lactams **7** in high yields (Figure 4).⁸

The tin hydrides could be replaced by a combination of silanes and catalytic amounts of a thiol under polarity reversal catalysis (PRC). The triethylsilane/*tert*-dodecanethiol system can promote the reduction of aromatic azides **8** to anilines **9**. The use of Bu_3GeH as a reductant in lieu of Et_3SiH has been reported too. However, both reductive systems failed to reduce aliphatic azides (Figure 5).⁹

Another synthetically useful mediator for radical chain reactions is indium hydride (InCl_2H), which is generated *in situ* from $\text{Et}_3\text{SiH}/\text{InCl}_3$ or $\text{NaBH}_4/\text{InCl}_3$. This reagent can substitute tin

Figure 4 Intramolecular addition of *N*-stannylaminyl radicals onto carbonyl groups/ β -fragmentation.

Figure 5 Radical reduction of aromatic azides with triethylsilane under polarity reversal catalysis.

Figure 6 Generation of indium-aminyl radicals and intramolecular addition onto nitriles.

hydrides in various transformations, first and foremost the reduction of halides. InCl_2H can also reduce aromatic and aliphatic azides at low temperature. The *N*-indium-substituted aminyl radical intermediate **10** can subsequently participate in intramolecular cyclization onto nitriles (Figure 6).¹⁰

Figure 7 Radical allylations by reaction of alkyl azides with allylindium dichloride.

Allylindium dichloride proved to be a valuable reagent for promoting radical allylation of azido compounds. Under UV light irradiation, photolysis of allylindium dichloride leads to the dichloroindyl radical, which can react with alkyl azide **11** to generate indium-aminyl radical **12**. The latter can then undergo intramolecular 1,5-H abstraction followed by allylation of the resulting radical **13**. Allyllactam **14** was obtained in good yield after hydrolysis (Figure 7).¹¹

Reduction of organic azides to *N*-centered radicals can in some cases be promoted by iron(II) complexes. Treatment of acyl and oxycarbonyl azides with a catalytic amount of FeCl_2 and trimethylsilyl chloride (TMSCl) in ethanol (or isopropanol) results in the formation of lactams and oxazolidinones, respectively. A radical pathway is proposed that involves the formation of an iron amidyl-type radical as intermediate and its subsequent cyclization to either alkene or alkyne functionalities. The sequence ends by the incorporation of a chlorine atom, which differs from the indium case (Figure 8).^{12,13}

In contrast, carbon-centered radicals react with organic azides exclusively in an intramolecular manner, providing cyclic aminyl radicals. Murphy designed radical cascades for the construction of the aspidospermidine, vindoline, and horsfiline cores, which included this key step (Figure 9).^{14–16}

An extension to the generation of amidyl radicals from acyl radicals was proposed by Benati, Spanolo, and Strazzari. Tin-mediated aryl radical cyclization onto thioester **15** derived from an iodoarylthiol led to the formation of acyl radical **16**, which underwent intramolecular addition to the azido group. In the presence of allyltriphenylstannane, the

Figure 8 Iron(II)-catalyzed intramolecular chloroamination of 2-alkenyloxycarbonyl azides and 2-alkynyloxycarbonyl azides.

Figure 9 Intramolecular addition of alkyl radicals onto alkyl azides.

transient amidyl radical **17** could be allylated and the corresponding indolinone derivative **18** was isolated in 60% yield (Figure 10).¹⁷

Vinyl azides are of particular interest because they are precursors of iminyl radicals. In 1997, Montevocchi reported the addition of the thiophenyl radical to α -azidostyrene and suggested that the α -azidobenzyl radical intermediately and spontaneously β -eliminated nitrogen to deliver an iminyl radical.¹⁸

Chiba later used it as a partner in manganese(III)-catalyzed tandem reactions with 1,3-dicarbonyl compounds. This sequence provides access to polysubstituted NH pyrroles. The best results were obtained with β -keto esters and Mn(OAc)₃·2H₂O as oxidative catalyst. This may

Figure 10 Intramolecular addition of acyl radicals onto alkyl azides and subsequent allylation.

Figure 11 Manganese(III)-mediated reaction of 1,3-dicarbonyls with vinyl azides.

involve sequential addition of β -keto ester radical—generated by Mn(III) enolate oxidation—to the vinyl azide, followed by evolution of N₂, cyclization of the resulting iminyl radical onto the ketone carbonyl and final dehydration to the pyrrole (Figure 11).¹⁹ Similar experiments were carried out with cyclopropanols, which led to either substituted pyridines or 2-azabicyclo[3.3.1]non-2-en-1-ols in excellent yields (Figure 12).²⁰ By analogy, Spagnolo examined the behavior of aryl azides toward carbon-centered radicals. Intramolecular ipso cyclization of aryl radicals of anilide derivatives at the para position of aromatic azides led to cyclohexadieniminyl radical intermediates which provided indolones and quinolones bearing either spirocyclohexadienimine or spirocyclohexadienone rings (Figure 13).²¹

Figure 12 Manganese(III)-mediated reaction of cyclopropanols with vinyl azides.

Figure 13 Intramolecular ipso addition of aryl radicals onto aromatic azides.

2.1.2 From Hydrazine Compounds

Hydrazine derivatives can also serve as precursors to nitrogen-centered radicals. As illustrated by Studer, carbamoyl radicals can be generated from N-aminated Hantzsch esters under conditions of PRC, and were shown to participate in anti-Markovnikov hydroamination of alkenes. This process takes advantage of the ability of the thiophenyl radical to activate the C–H bonds of dihydropyridines owing to polarity matching and then to generate carbamoyl radical (BocNH $\cdot$) after subsequent N–N bond cleavage. Finally, the liberated radical could be trapped by terminal and 1,2-disubstituted double bonds in moderate yields (Figure 14).²² Thiosemicarbazide derivatives also

Figure 14 Radical hydroamination of olefins with N-aminated dihydropyridines under PRC.

Figure 15 Synthesis of the forticine core through an amidyl radical cascade reaction.

showed a propensity for providing amidyl radicals. An elegant application to the synthesis of the natural product forticine was proposed by Zard (Figure 15).^{23,24}

2.1.3 From Triazene Compounds

Another class of functional groups for the generation of N-centered amidyl radicals includes

Figure 16 Cyclization of amidyl radicals generated from *N*-acyltriazenes.

N-acyltriazenes whose reactivity has been briefly examined. Thermolysis of unsaturated *N*-acyltriazenes in toluene releases amidyl radicals, which undergo intramolecular 5-*exo* cyclizations to form γ -lactams. With more substituted substrates, a cascade radical cyclization involving sequential 5-*exo* cyclization/homolytic aromatic substitution led to tricyclic lactams (Figure 16).²⁵

2.2 N-Centered Radicals by Homolytic N–S Bond Cleavage

2.2.1 From *N*-Thioaryl Compounds

Sulfenamine and sulfenylamide derivatives have been successfully employed for the generation of N-centered radicals by homolytic cleavage of the N–S bond. As reported by Li, treatment of *N*-(benzenesulfonyl)pent-4-enylamines with the Bu₃SnH/AIBN system affords the corresponding aminyl radicals which can cyclize onto the alkene moiety providing a mixture of pyrrolidines and piperidines. As usual, the nature of the substituents on the alkene is critical for controlling the product distribution. For instance, cyclization of pent-4-enylaminyl and 4-methylpent-4-enylaminyl radicals gave preferentially the 5-*exo* products, while the 4-chloro-substituted radical gave the 6-*endo* adducts. It is also worthy of note that the cyclization of primary aminyl radicals is much more

Figure 17 5-*exo* versus 6-*endo* cyclization of primary 4-substituted pent-4-enylaminyl radicals.

Figure 18 Intramolecular addition of primary amidyl radicals to C=C double bonds.

efficient than that of secondary aminyl radicals (Figure 17).²⁶

Lessard examined the intramolecular addition of primary amidyl radicals to olefins. Under standard tin hydride conditions, *N*-(phenylthio)amide precursors **19** underwent 5-*exo*-trig cyclizations exclusively to give γ -lactams **20** (Figure 18).²⁷ The behavior of 5-hexenamidyl radicals has been studied by Li. Theoretical calculations and deuteration experiments showed that the reaction of primary amidyl radicals favors the formation of the 6-*endo* products while its *N*-*tert*-butyl counterpart undergoes 1,5-hydrogen abstraction.²⁸ Additional studies examined the effect of the substitution of the vinylic function on the regioselectivity of *N*-(4-pentenyl)aminyl radical cyclization. The presence of heteroatoms (Cl, OMe, SEt) in the internal position results in the exclusive formation of the 6-*endo* products.²⁹

Figure 19 Cyclization of amidyl radicals generated from *N*-(*O*-ethyl thiocarbonylsulfanyl)amides.

2.2.2 From *N*-Thiocarbonylsulfanyl Compounds

N-(*O*-Ethyl thiocarbonylsulfanyl)amides are of particular interest because they are both precursors of amidyl radicals and able to perform xanthate transfer reactions. As reported by Zard, a catalytic amount of lauroyl peroxide (DLP) can initiate the homolysis of the N–S bond of **21** and generate an amidyl radical. The latter adds intramolecularly to a double bond. Then, the resulting cyclized radical **23** reacts with another molecule of *N*-(*O*-ethyl thiocarbonylsulfanyl)amide and propagates the radical chain process. The addition of an extra equivalent of DLP to the pyrrolidinone derivative **24** triggers an intramolecular homolytic aromatic substitution (see **Radical Arylations**) to form the tetracyclic product **22**. The same compound can also be obtained directly, starting from a stoichiometric amount of DLP (Figure 19).³⁰

2.2.3 From *N*-Allylsulfonyl Compounds

N-Allylsulfonylamides also lead to amidyl radicals. Sequential xanthate radical addition to the allyl moiety followed by β -fragmentation led to the *N*-amidosulfonyl radical. Depending on the substitution at N, extrusion of SO₂ can follow. With *N*-phenyl derivatives, the amidyl radical can be formed and then undergo a 5-*exo*-trig cyclization. In turn, the newly formed radical can add to the xanthate, regenerate the tertiary alkyl radical, and then propagate the chain. When *N*-allylsulfonylamides

Figure 20 Generation of *N*-amidosulfonyl and amidyl radicals from *N*-allylsulfonyl compounds and subsequent cyclization reactions.

are substituted by an ethyl group instead of a phenyl, ring closure of *N*-amidosulfonyl radicals occurs more rapidly than the loss of sulfur dioxide (Figure 20).³¹

2.3 N-Centered Radicals by Homolytic N-Halogen Bond Cleavage

Photochemical activation can allow the cleavage of N-halogen bonds, which constitutes one of the most efficient ways to generate N-centered radicals. The formation of substrates bearing N-halo bond has been achieved by electrophilic halogenations of amines, amides, or sulfonamides. These substrates are sufficiently stable to be isolated, and they can also be generated *in situ*. A one-pot N-halo bond formation/homolysis reaction has been applied to the formation of aziridiny radicals (Figure 21).³² The reaction of aziridine **25** with *N*-bromosuccinimide (NBS) or *N*-iodosuccinimide (NIS) yields the corresponding *N*-bromo or *N*-iodo aziridine **26** which undergoes N–X bond homolysis

Figure 21 Aziridiny radical formation and addition onto alkenes.

to form aziridiny radical **27**, which adds onto styrenes. Termination occurs by either bromination or by iodination. By using *N*-chlorosuccinimide (NCS) as the halogenation reagent, no reaction was observed, which can be indicative of a less favorable homolysis of a N–Cl bond compared to N–Br or N–I. A cationic process was excluded, since the addition of galvinoxyl radicals resulted in complete inhibition. The same effect has been observed in the absence of light, providing further strong evidence for a radical process.

Aminyl radicals can also be generated by reduction processes of the N–X bond. In the presence of copper(I) salts, the *N*-chloramine **28** has been converted to piperidiny derivatives **29** (Figure 22).³³ Single-electron transfer (SET) from copper(I) catalyst allows the reduction of the N–Cl bond to generate the radical cation **30**, which undergoes a 5-*exo*-trig cyclization to afford the pyrrolidiny intermediate **31** and release the copper(II) complex. The primary radical formed reacts through a second SET process, leading to the formation of the corresponding chlorinated pyrrolidine **32** and the regeneration of the catalyst. The primary chloride **32** undergoes a subsequent stereoselective ring expansion to yield compound **29**.

Cyclizations have also been reported to adopt a chair-like Beckwith–Houk transition state. The copper(II) center not only allows the activation of the aminyl radical but also coordinates to the alkene to access a more rigid transition state and thus ensures better stereoselectivity. The stereoselectivity increased further in the presence of a stronger Lewis acidic complex (CuPF₆ vs CuCl) and more sterically demanding ligands (e.g., *N,N,N',N'*-tetramethylethylenediamine

Figure 22 Copper(I)-mediated formation of aminyl radical.

Figure 23 Copper(I)-mediated formation of amidyl radical.

(TMEDA) or *N,N,N',N'*-tetramethylcyclohexanediamine (TMEDA)). Diversely substituted piperidiny compounds can be obtained with selectivity up to 20 : 1.

The same type of transformation has been applied to the cyclization of amidyl radicals (Figure 23).³⁴ The *N*-chloramide substrate was prepared by deprotonation of amide **33** to form the corresponding amidyl anion, followed by quenching with NCS. Subsequent heating in methanol with a catalytic amount of copper(I) chloride allowed the formation of the chlorinated pyrrolidone **34** in 96% yield. Attempts to extend this methodology to the formation of *N*-centered carbamoyl radical led to low yields of the cyclized products.

Amidyl radicals are also generated by spontaneous homolytic cleavage of N-halogen bond. A two-step reaction sequence has been reported by Li starting from iodoacetamide **35** (Figure 24).³⁵ Atom transfer radical addition (ATRA, see **Halo-**

Figure 24 Reactivity of amidyl radical in atom transfer radical addition.

Transfer Radical Polymerization (ATRP) and Addition (ATRA) and Applications) reaction initiated by triethylborane has been conducted with 1-hexyne in the presence of $\text{BF}_3\cdot\text{OEt}_2$ to afford the vinyl iodide derivatives **36**. Subsequent treatment with $t\text{-BuOCl}/\text{I}_2$ system allows the *in situ* formation of the corresponding *tert*-butyl hypoiodite, which generates the N–I bond. Homolytic cleavage of this bond yields the amidyl radical, which cyclizes through a 5-endo-trig mode. Radical **38** evolves through a β -scission reaction to form lactam **37**, which reacts with iodine to afford either iodide **39** or diene **40**, depending on the nitrogen substituent (R).

N-Chlorosulfonamide derivatives exhibit good ability as sulfonamidyl radical precursors. The irradiation of *N*-chlorosulfonamide **41** by a 125-W high-pressure mercury lamp allowed the homolytic cleavage of the N–Cl bond and the subsequent cyclization of the resulting *N*-tosyl aminyl radical (Figure 25).³⁶ The 5-*exo*-trig and 6-*endo*-trig cyclization products, **42** and **43** respectively, were obtained in favor of the six-membered ring due to the internal substitution of the olefin. The incorporation of a chlorine atom in the products is the result of an atom transfer step in the radical chain process. The same transformation was also reported under chemical initiation with the triethylborane (cat.)/ O_2 system, providing strong evidence for a radical chain reaction.

Figure 25 Reactivity of sulfonamidyl radical in atom transfer radical addition.

Figure 26 [3 + 2] Annulation sequence through sulfonamidyl radical.

A [3 + 2] annulation sequence has been reported by Oshima for the *N*-allyl-*N*-tosylamidyl radical (Figure 26).³⁷ Chlorine abstraction from triethylborane/ O_2 enables a radical cascade of N-centered radical **45** featuring an intermolecular addition followed by 5-*exo*-trig cyclization to the pyrrolidinyl derivative **44**. The primary radical formed undergoes chlorine transfer to regenerate **45**. Aminyl and amidyl radicals were not suitable, since they were reduced by hydrogen transfer from the allylic position prior to cyclization.

An interesting use of *N,N*-dichlorosulfonamide **46** as a diradical equivalent has been reported for the preparation of disubstituted pyrrolidine derivatives (Figure 27).³⁸ Using triethylborane as radical initiator, *N*-chloro-*N*-sulfonamidyl radical was formed to add onto 1,3-dienes to yield the corresponding chlorinated *N*-chloro-*N*-allylsulfonamide resulting from an atom transfer process. The second radical addition can be performed with the isolated intermediates or in a one-pot two-step sequence. For the second reaction step, the second olefin and a catalytic amount of triethylborane were directly added to the crude mixture. Then, a second atom transfer process (ATP) proceeded leading to the formation of 1,2-dichlorinated compounds. This sequence was applied to a variety of radical acceptors. For

Figure 27 *N,N*-Dichlorosulfonamide as a diradical equivalent.

Figure 28 Copper(I)-catalyzed N–O homolysis for the formation of aminyl radical.

example, 1,3-butadiene and styrene reacted in these conditions to afford **47** in 91% yield.

2.4 N-Centered Radicals by Homolytic N–O Bond Cleavage

Aminyl radical can enter group transfer reactions initiated by copper(I)-catalyzed reduction of N–O bonds in *N*-benzoyloxyamines such as **48** (Figure 28).³⁹ The copper(II)–benzoyl complex formed during the reduction step transfers the acyl group to the primary C radical obtained after cyclization, which allows the regeneration of the catalyst. No reaction was observed without Lewis acid, indicating that the acyloxy group must be activated to weaken the N–O bond. Boron trifluoride is the best activator (79% yield).

Similarly, the *N*-benzoyloxyamidyl group has been used for the formation of amidyl radicals in the total synthesis of alkaloids. In this case, a tributylstannyl radical added onto the oxygen atom of the benzoyl group, leading to fragmentation of the N–O bond of **49** (Figure 29).⁴⁰ The resulting amidyl radical **50** underwent a radical cascade which provided an entry toward (±)-deoxyserratine. Note that a second equivalent of tributyltin hydride

Figure 29 Amidyl radical formation by addition of tributylstannyl radical onto *N*-benzoyloxyamidyl group.

Figure 30 Fragmentation of sulfinate and phosphonate derivatives of hydroxamic acids as precursor of the amidyl radical.

is needed to remove the chlorine atom used to direct the final 6-*endo*-trig cyclization. The same concept has been applied to the total synthesis of (±)-aspidospermidine.⁴¹

The formation of amidyl radicals has been also induced by the fragmentation of sulfinate and phosphonate derivative of hydroxamic acids (Figure 30).⁴² The *in situ* formation of such intermediates has been performed by the treatment of **51** with *tert*-butylsulfinyl or diethylphosphonyl chloride in the presence of diisopropylethyl amine at –50 °C. Upon increase of the reaction temperature, a spontaneous homolytic cleavage of the N–O bond gave the corresponding amidyl radical.

This transformation has been applied to oxime substrates to generate iminyl radicals. The primary C-centered radicals resulting from 5-*exo*-trig cyclizations were trapped with either diphenyl diselenide or 2,2,6,6-tetramethylpiperidinoxyl (TEMPO) to obtain the pyrrolidones **52** in good yields. β-Tosylethylhydroxylamine was subjected to the same conditions to afford the analog amidyl radicals, which allowed a facile deprotection of the amide function.⁴³

Iminyl radicals are certainly the most studied nitrogen-centered radical and can be obtained under a variety of experimental conditions.⁴⁴

Figure 31 Photochemical formation of iminyl radical by activation of acyloxime derivatives.

With photochemical activation, the N–O bond of biphenyl acyloxime **53** is cleaved to generate the corresponding iminyl radical **54** (Figure 31).⁴⁵ An intramolecular arylation delivered phenanthridine derivative **55** in high yield. Intermolecular and intramolecular addition onto various unsaturated acceptors such as arenes, alkenes, or alkynes have been reported. Some theoretical and photochemical studies have been made on such systems.⁴⁶ This convenient transformation has found applications in natural product synthesis.⁴⁷ An analogous transformation involving dioxime oxalates as radical precursors has been reported by Walton.⁴⁸

Redox processes have proven to be highly efficient in the context of iminyl radical formation, allowing experimental conditions to be compatible with organic synthesis. This type of transformation mainly involves reduction steps of the N–O bond either by organic or organometallic compounds. *O*-Acyl and *O*-methyloxime **56** were allowed to react under photochemical irradiation in the presence of a catalytic amount of 1,5-dimethoxynaphthalene (DMN) and 1,4-cyclohexadiene (1,4-CHD) to yield the corresponding cyclic imine **57** in good yield (Figure 32).⁴⁹ The photoactivated DMN reduced **56** by an SET process to generate the radical anion $[56]^{*-}$. Then, the fragmentation of the N–O bond gave the iminyl radical, which cyclized by a 5-*exo*-trig pathway to afford the radical intermediate **58**. By a hydrogen transfer from the 1,4-CHD, the final product **57** was obtained and the reduction of $[DMN]^{*+}$ occurred to regenerate the photosensitizer DMN. No reaction was observed without the DMN, indicating that these N–O bonds cannot be cleaved at wavelengths above 300 nm. Extensions of this reaction are possible with other photosensitizers and radical acceptors.^{50,51}

Figure 32 Photochemical/single-electron transfer sequence for iminyl radical formation.

Figure 33 Single-electron transfer process for the formation of the iminyl radical.

SET was also investigated under transition-metal catalysis. Ir(I) complex in the presence of pyridinyl ligands was able to reduce the N–O bond of **58** to afford the corresponding iminyl radical **59** (Figure 33).⁵² Strain release evolved through a fast β -scission reaction and gave rise to the resulting nitrile function. In the presence of 9,10-dihydroanthracene, the radical intermediate **60** has been reduced by hydrogen transfer. Besides, diphenyl diselenide $(PhSe)_2$ was used as a radical trap for **60** to form a C–Se bond.

The homolytic cleavage of the N–O bond can also be triggered by microwave irradiation. This works

Figure 34 Microwave-assisted homolysis of N–O bond of *O*-phenyl oxime.

best with weak bonds such as *O*-phenyl oxime ethers (bond dissociation energy (BDE) ($R_2C=N-OPh$) = 140 kJ mol^{-1} for $R = \text{Me}$ or Ph).⁵³ The substrate **61** was used as the iminyl radical precursor, which was able to cyclize and afford the imine derivative **62** in good yield (Figure 34).⁵⁴ The reaction was conducted in toluene, which allowed the reduction of the phenoxyl radical by hydrogen transfer. One equivalent of ionic liquid emimPF_6 was necessary to increase the microwave absorbance level of the reaction medium. This reaction was extended to other radical acceptors that trapped the iminyl radical in an intra- or intermolecular manner. The syntheses of quinazolines and dihydroquinazolines derivatives were reported by using imines as radical acceptor.^{55,56} Conversely, one can also look at this process as an efficient pathway to generate aryloxy radicals.⁵⁷

2.5 N-Centered Radicals by Homolytic N–C Bond Cleavage

Cleavage of N–C bonds is an interesting yet rare path to nitrogen-centered radicals. Such bonds are generally too strong to lead to efficient homolytic cleavage, and β -amino radicals thus do not undergo radical β -elimination easily. However, Taguchi and coworkers took advantage of the ring strain in aziridines to generate N-centered radicals via such a process. The opening is regioselective and favors the formation of electrophilic *N*-tosylamino radicals rather than the α -amino ones.

Primary radical **63** underwent strain-release-driven C–N radical β -elimination. The N radical **64** was engaged in a [3 + 2] cycloaddition manifold with electron-rich alkenes to form the corresponding substituted pyrrolidine in good yield (Figure 35).⁵⁸ A similar radical pathway was later applied by Speybroeck,⁵⁹ Prévost,⁶⁰ and Shipman,⁶¹ to intramolecular processes.

Figure 35 Formation of *N*-tosylamino radical by opening of aziridines.

In 2002, Prévost and Shipman showed that N-centered radical can also be generated from 2-methyleneaziridines by intramolecular addition of alkyl radical onto *exo*-methylene and subsequent β -elimination.^{59,60} Here again, the relief of the high ring strain was the promotor of the cleavage of the nitrogen–carbon bond, leading to an aminyl radical. In fact, the ring strain of the 2-methyleneaziridine is $12\text{--}13 \text{ kcal mol}^{-1}$ higher than for the aziridine; however, these species are still very stable.

In this article,⁶⁰ the 2-methyleneaziridine produced an alkyl radical in the presence of Bu_3SnH and AIBN, which cyclized only on the *exo* mode (Figure 36). This was then followed by the opening of the aziridine and the formation of the nitrogen-centered radical. Piperidines were synthesized with good yields, even in the case where the intermediate was a stable tertiary radical. This new method offered the possibility to synthesize piperidines and bicycles using radical rearrangements with total regioselectivity.

Alternatively, rearomatization can be harnessed to bring the energy required to cleave the C–N bond.⁶² Hydrogen atom abstraction from 1,4-cyclohexadiene derivative **65** enables the C–N bond fragmentation by releasing an aromatic by-product (Figure 37). Nitrogen radical addition to norbornene followed by H-atom transfer from **65** allows the formation of the hydroaminated norbornane and the propagation of the radical cycle. It was later shown that unactivated and electron-rich olefins can be hydroaminated under these conditions.⁶³ Better yields were obtained when thiophenol was used as a catalyst and a high anti-Markovnikov selectivity was observed. Besides, one of the most important advantages of

Figure 36 Formation of an aminyl radical from a 2-methyleneaziridine.

Figure 38 Radical Smiles rearrangement starting from a xanthate.

Figure 37 Synthesis of hydroaminated norbornane by rearomatization of 1,4-cyclohexadiene derivative **65**.

this synthesis was the good tolerance toward functional groups such as bromides, imides, alcohols, or amides.

A last example of the rupture of a nitrogen–carbon bond was reported by Zard *et al.*, when they observed an unusual radical Smiles rearrangement starting from a xanthate (Figure 38).⁶⁴

2.6 N-Centered Radicals by Homolytic N–H Bond Cleavage

The generation of N-centered radicals can be achieved through formal N–H bond cleavage of

Figure 39 Oxidation of anilnamides mediated by IBX.

aminyl, amidyl, or similar functional groups. It is in fact an electron coupled to a proton transfer carried out with hypervalent iodine oxidants. For example, Nicolaou *et al.* reported the oxidation of anilnamides by 2-iodoxybenzoic acid (IBX), which generates an anilnamidyl radical **66** that can undergo 5-*exo*-trig cyclizations to δ -lactams (Figure 39). As shown by the authors in mechanistic studies, the solvent plays an important role in the termination step. However, some steps of the mechanism are still not clear. But the method offers a convenient way for the synthesis of various compounds such as cyclic urethanes, hydroxylamines, and sugars.⁶⁵

Following a similar principle, Suarez presented the formation of amidyl radicals using $\text{PhI}(\text{OAc})_2$ and I_2 (see **Radicals and Carbohydrates**). In a sugar, this N radical **67** undergoes 1,6-intramolecular hydrogen transfer to re-form the amide and the anomer radical **68**. Oxidation of the latter generates an oxonium which is trapped by

Figure 40 Formation of amidyl radicals using $\text{PhI}(\text{OAc})_2$ and I_2 .

Figure 42 Addition of nitrogen and carbon radicals onto nitriles and imines.

Figure 41 Intramolecular carboamination of alkenes.

the amide to form spirolactams (Figure 40).⁶⁶ Similarly, 2-amino-*C*-glycosides can be transformed into oxa-aza spirobicycles.^{67,68}

The oxidation of tosyl-*o*-allylanilines has also been investigated by using $\text{Cu}(\text{OAc})_2$ and Cs_2CO_3 at 120°C . As a result, tosylaniliny radicals **69** were formed and cyclized in a 5-*exo*-trig mode.⁶⁹ This intramolecular carboamination of alkenes can be used for the synthesis of hetero-polycyclic compounds (Figure 41).^{70–73}

2.7 N-Centered Radicals by Radical Addition onto Nitrile or Imine Derivatives

Iminyl or aminyl radicals can be generated by radical addition to cyano or imino functional groups, respectively. As shown below, either a carbon- or nitrogen-centered radical can add at the carbon atom of the cyano or imino moiety, producing a new nitrogen radical.⁷⁴ This is illustrated by the two examples shown below in which radical ring closure onto nitriles forms cyclic amidines,⁶ while the addition of isopropyl radical to imines leads to amines (Figure 42).⁷⁵

In addition, radical fragmentation (retroaddition) can also take place and result in the re-formation of the starting functional group (Figure 43). Interestingly, cyano group transfer can be observed to occur through a 5-*exo* or 6-*exo* cyclization/ring-opening sequence.^{76,77}

Most of the examples in the literature report cascade reactions of iminyl radicals formed through intramolecular radical addition to cyano groups.^{7,78–83} These cascades can be initiated either by reducing agents—such as SmI_2 -initiated reduction of aryl halides—(Figure 44a),⁸⁴ or by radical mediators (Figure 44b and c, respectively).^{76,85} Radicals formed under these conditions undergo cyclization cascades that are intermediated by either iminyl or aminyl radicals.

Figure 43 Cyano group transfer through radical cyclization/ring-opening cascade.

3 OXYGEN-CENTERED RADICALS

Formation of oxygen-centered radicals has been widely described in the literature for almost 50 years.^{86,87} They have been generally generated from many R–OX species under different conditions (Figure 45).

It is also known that alkoxy radicals are very reactive and can be used as strategic intermediates in organic synthesis. Indeed, these radicals exhibit three major reactivities, namely, hydrogen atom transfer (HAT), β -scission, and additions onto unsaturations. The following sections will attempt to describe recent advances in the generation of alkoxy radicals and their reactivities in the order given above.

Figure 44 Radical cyclization cascades where iminyl and aminyl radicals occur as intermediates.

Figure 45 Formation of oxygen-centered radicals.

3.1 Formation of Alkoxy Radicals from RO–X Compounds

More than a dozen methods to generate alkoxy radicals before 2000 have been described and summarized by Čeković in a review.⁸⁸ The wide variety of conditions and substrates allow this method to be applied to organic synthesis. Indeed, we can find families of precursors such as alkyl hypohalites, nitrites, peroxy compounds (hydroperoxides, dialkylperoxides, and peroxyacetates), and *N*-alkoxy phthalimides. The conditions used can be photolysis, thermolysis, or oxidation. A main advance in this field was made by Beckwith, who showed in 1988 that *N*-alkoxy-pyridine-2(1*H*)-thiones were clean sources of alkoxy radicals.⁸⁹ Hartung

Figure 46 Two steps to alkoxy-4-methylthiazole-2(3)-thiones.

followed up on this chemistry by first using these derivatives and then proposed the valuable alternative alkoxy radical precursors.^{90,91} Indeed, he has recently developed a method to access alkoxy-4-methylthiazole-2(3)-thiones **70** in good yields in two steps (Figure 46). On this occasion, he studied the influence of substituents on the absorbance wavelength and also made spin-trapping experiments using the nitron 3,4-dihydro-2,2-dimethyl-2*H*-pyrrole-1-oxide (DMPO), monitored by electron paramagnetic resonance (EPR).^{92,93}

This method has also been used by the same team to form precursors that were engaged in reactions to show classical reactivities of alkoxy radicals such as 5-*exo* cyclization, 1,5 HAT, or β -scission.⁹⁴

Newcomb has also proposed 4-nitrobenzenesulfonate esters (such as **71**) as precursors of alkoxy radicals.⁹⁵ Indeed, these compounds can easily perform an O–S bond homolysis to give the desired alkoxy radical using laser flash photolysis by irradiation at 355 nm (Nd:YAG third harmonic) (Figure 47).

More recently, methods have been described using catalytic amounts of metal salts. For instance, the formation of alkoxy radicals from 1-phenylcyclopropanols has been described with catalytic amounts of complexes of manganese(III)²⁰ silver(I),⁹⁶ or cobalt(II) in each case, in the presence of an oxidant.⁹⁷ Applications of these procedures are discussed.

Figure 47 O–S bond homolysis.

Figure 48 Six-membered ring chair-like conformation.

3.2 Reactivity

3.2.1 Hydrogen Atom Transfer

As mentioned earlier, HAT is a prominent reaction of alkoxy radicals.⁸⁸ While this has been known for a long time, the main questions remain: What factors are leading this reactivity? What conditions should be used? Can this process be useful in organic synthesis? The most common abstraction in the literature is the 1,5 HAT,⁹⁸ which requires, as modeled by Houk,⁹⁹ a six-membered ring in the lowest energy chair-like conformation of Figure 48.

Other HATs such as 1,6 and 1,4 are not favored. In the case of a 1,6 HAT, a seven-membered ring is involved, which is entropically disfavored. We can nevertheless find, in the literature, this HAT applied to rigid systems, with the right distance between the O-radical, the hydrogen, and the carbon in the δ position.¹⁰⁰

Recently, Sammis *et al.* have highlighted the use of 1,5 HAT to form cyclopentyl, tetrahydrofuran, and pyrrolidine derivatives through the homolysis of *N*-alkoxy phthalimides in the presence of AIBN and tributyltin hydride.¹⁰¹ The reaction is interesting because it involves two key radical steps in one reaction. First, the alkoxy radical reacts via 1,5 HAT to give a secondary carbon-centered radical **72**. Then, this new radical performs a 5-*exo*-trig cyclization giving five-membered ring substrates as a mixture of diastereomers, the *cis* being the major

Figure 49 Hetero five-membered rings from *N*-alkoxy phthalimides homolysis.

Figure 50 Application to a fragment of (–)-amphidinolide K.

one in accordance with the Beckwith–Houk model (Figure 49).

This principle could be applied to the synthesis of a fragment of (–)-amphidinolide K, starting from enantiopure precursor **73** (Figure 50).

HAT is also a very powerful tool if it is well controlled. As an example, Suarez *et al.* used a very rare 1,8 HAT between glucopyranose units in a disaccharide template such as **74** (Figure 51).¹⁰² The conformational restriction of this system minimizes the entropic cost associated with the assembly of a transient nine-membered ring. Conversely, the C6–O···H–C5' distance has been estimated to 2.5 Å. Thus, in the presence of 1.5 equiv of (diacetoxyiodo)benzene (DIB) and 0.7 equiv of iodine, an alkoxy radical (**75**) is generated that performs the 1,8 HAT, which engenders a tertiary C-centered radical (**76**) in the β -position of an acetate group. That proximity affords the reversible formation of a five-membered ring by creating a C–O bond through a quite unusual 5-*endo*-trig radical cyclization. The

Figure 51 Example of 1,8 HAT.

resulting radical intermediate **77** is oxidized to give the corresponding oxonium cation, which is subsequently trapped by the pendant alcohol to give the desired compound. This access to 4-D-Glc disaccharides can be of interest in the chemistry of heparin analogs.

As seen previously, HAT requires a hydrogen at the right distance from the alkoxy radical to be efficient. If not, we can observe another reactivity called β -scission, which is discussed in the next subsection.

3.2.2 β -Scission

β -Scission consists in a homolytic bond breaking following an alkoxy radical formation and can be influenced by reaction conditions such as solvent or temperature. Indeed, as recently compiled by Ingold in a review, solvents play a role in the β -scission kinetics (see Figure 52).¹⁰³ For instance, hydroxylated solvents accelerate the β -scission compared to aromatic ones.

The β -scission acceleration can be explained by the fact that the solvation of the carbonyl species

Solvent	$T(K)$	$k (10^6 \text{ s}^{-1})$
$\text{PhCMe}_2\text{O}^\bullet \rightarrow \text{PhC(=O)Me} + \text{Me}^\bullet$

{ PhCl + 0.4 M EtOH	238	10.7

Figure 52 Solvent effect in the β -scission kinetics.

Figure 53 Competitive reactions.

that are formed is better than the solvation of its alkoxy radical precursors.

Despite the solvent effect, the stability of the product radical matters in the rates of radical loss. In the first reaction (Figure 52), if we have the R radical (with R = Et, *i*-Pr, *t*-Bu, PhCH₂), instead of the Me one we can notice that the reaction speed increases with the substitution. The rate constant is estimated at $5 \times 10^6 \text{ s}^{-1}$ for propyl versus $2 \times 10^8 \text{ s}^{-1}$ for benzyl.

Logically, Newcomb *et al.* highlighted in 2000 that temperature has an influence on the rates of β -scission and of 1,5 HAT and compared both reactivities.⁹² They showed that the rate of β -scission decreases with temperature. They also observed the same phenomenon with 1,5 HAT but noticed that $k_{1,5 \text{ HAT}}$ decreases more slowly than $k_{\beta\text{-scission}}$. For example, the alkoxy radical **78** can undergo 1,5 HAT or β -scission (Figure 53). Measurements show that 40% of products come from the β -scission at 50 °C instead of 21% at 10 °C. A prototypical case of 1,5 HAT involving an alkoxy radical and a secondary alkyl position gave a value of $2.7 \times 10^7 \text{ s}^{-1}$.

This reactivity can be used in intramolecular reactions such as ring expansions. The following example by the Hasegawa group in 2007 shows

Figure 54 Example of intramolecular reactions.

some possibilities of β -scission which depends on the substrate structure (ring size, *n*) and reaction conditions.^{104,105} Thus, when cyclopropyl silyl ether **79** is treated with 2 equiv of tris-*p*-bromophenylaminium hexachloroantimonate (TBPA), a well-known hole catalyst, the chloro derivative is formed. Subjecting this crude product to NaOAc in MeOH provides cycloheptenone **80** in 52% overall yield. In contrast, upon treatment with 0.1 equiv of 9,10-dicyanoanthracene (DCA) and 1.2 equiv of biphenyl (BP) in MeCN under irradiation (Photoinduced electron transfer (PET) conditions, $\lambda > 340 \text{ nm}$), bicyclic ketone **81** is obtained in 59% yield (Figure 54).

This difference of outcome is rationalized by external or internal bond cleavage. In the presence of an oxidant (second equivalent of TBPA), the

Figure 55 Alkoxy radicals involving heteroatomic partners.

formation of a tertiary carbocation **82** will drive the reaction to the internal cleavage; on the contrary under PET conditions, oxidizing species have short lifetimes and radical processes from the external cleavage such as 5-exo cyclization can take place (**83**).

β -Scissions from alkoxy radicals can also involve heteroatomic partners such as phosphorus- or sulfur-centered radicals.¹⁰⁶ This study brought to light an interesting dependence of a tandem process on the nature of the leaving group. Thus, in the case of an acylsulfide precursor, the first reaction that occurs is a 5-exo cyclization followed by the addition on the acyl group to form the corresponding alkoxy radical intermediate. Homolytic cleavage of the C–S bond gives the final product **84**. In the case of the acyl phosphonate, however, the 5-exo cyclization does not occur. The major product **85**

corresponds to the addition on the acyl phosphonate (6-exo cyclization) and the leaving of the phosphonate group. The difference of reactivity can be explained by the fact that the acyl phosphonate is a better radical acceptor than acyl sulfide (Figure 55).

Recently, the β -scission of diversely substituted cyclopropanols has triggered interest in the synthetic community. Narasaka has shown that various β -keto radicals were generated in the presence of a catalytic quantity of AgNO_3 and $(\text{NH}_4)_2\text{S}_2\text{O}_8$ as a reoxidant and pyridine. Good yields of addition products to enolethers such as **86** have been observed. Even more versatile is the possibility to accomplish three-component couplings with electron-deficient and electron-rich alkenes as in **87**, in this order because of the nucleophilic character of the initial β -keto radical (Figure 56).

Chiba nicely followed up on this by devising a Mn(III)-catalyzed or mediated synthesis of pyridine and 2-azabicyclo[3.3.1]non-2-en-1-ol derivatives from cyclopropanols and vinylazides (Figure 57).

This formal [3 + 3] annulation of vinyl azides and cyclopropanols proved useful for the total synthesis of the indole alkaloid of ($\pm$)-melinoline E (Figure 58).¹⁰⁷

3.2.3 Brook Rearrangement

Paredes and Alonso used α -silyl alcohols and α -silyl alcohol nitrite esters in the presence of lead tetraacetate.¹⁰⁸ In the case of alcohols, subsequent to the corresponding alkoxy radical generation, a

Figure 56 β -Scission of diversely substituted cyclopropanols.

Figure 57 Mn(III)-catalyzed synthesis of pyridine.

Figure 58 Synthesis of the indole alkaloid of (±)-melinoline E.

radical Brook rearrangement occurred, resulting in the formation of a secondary or tertiary C-centered radical which was reoxidized by lead triacetate. Finally, the cation was trapped by an acetate to deliver the final products (Figure 59).

It is also interesting to note that acylation is faster than 5-exo cyclization even if an electron

withdrawing group such as an ester is present in alkene α -position (Figure 60).

In the case of nitrites under light irradiation, with alkyl derivatives, formation of carbonyl species prevails. With aromatic substrate, no light is even required. Several mechanistic scenarios have been proposed (Figure 61).

3.3 Addition of Oxygen-Centered Radicals to π Systems

3.3.1 Intermolecular Reactions

The manipulation of oxygen-centered radicals for synthetic applications, especially in an intermolecular context, is particularly delicate because these types of intermediates are presumably just too reactive and can potentially give rise to undesired pathways. The work of Wille has certainly provided a good solution to circumvent this issue by developing the concept of self-terminating radical

cyclizations. It relies on the additions of O–X[•] radicals featuring spin density centered on the oxygen atom, X[•] being an easy radical to generate. First examples along these lines were given with the NO₃[•] radical, which can be conveniently formed by anodic oxidation of the nitrate anion or photolysis of ammonium cerium(IV) nitrate. Medium-sized cycloalkynes ($n = 8\text{--}12$), because of their intrinsically strong transannular interactions favoring subsequent intramolecular steps, were anticipated to be substrates of choice for these studies, which proved to be a good intuition. Thus, upon treatment of cyclodecyne with the electrochemically generated NO₃[•] radical, transannular cyclization took place and provided the formation of cis-fused bicyclic ketone **88** and the trans-fused one **89** in 70% yield in a 3:1 ratio.¹⁰⁹ Intermolecular addition of the NO₃[•] radical generates a highly reactive vinyl radical intermediate that is prone to undergo transannular hydrogen transfers. Not surprisingly, 1,5-H transfer prevails and gives rise to a secondary alkyl radical that further adds onto the vinyl ester function. Final fragmentation liberating the NO₂[•] radical completes the cascade of events and delivers the bicyclo[5.0.3]decanone system **88** as major product and as a single diastereomer. The other minor component originates from an initial 1,6-H transfer followed by the same type of elementary steps (Figure 62).

Other sources of <<O:>> synthon were tested with the Fenton-generated SO₄^{•-} radical and provided the same mixture of **88** and **89** in 80% yield in a 1.9:1 ratio¹¹⁰ and with acyloxy radicals¹¹¹ (RCO₂[•], R = Me, Ph, 4-OMe-Ph, etc.) resulting in yields up to 89%. The precursors used for the generation of the acyloxy radicals were *O*-acyl thiohydroxamate esters. Other O-centered radicals such as (alkoxycarbonyl)oxyl, ROC(O)O[•], [(alkoxycarbonyl)-acyl]oxyl, ROC(O)C(O)O[•], (carbamoyl)oxyl R₂N C(O)O[•], alkoxy radical, RO[•],¹¹² and nitroxyl radicals R₂NO[•]¹¹³ have been tested and have proved to be operative for the formation of **88** and **89**. Interestingly, even the hydroxy radical could be engaged (Table 1).¹¹⁴

Though beyond the scope of this article, it should be mentioned that N-centered (aminium and amidyl) and S-centered radicals have also been used in the context of self-terminating radical cyclizations.¹¹⁵

Interestingly, 5-cyclodecyne also proved to be an interesting substrate to study, since in that case further complexity is obtained thanks to the

Table 1 Influence of the O-centered radical source on the formation of **88** and **89**.

Entry	X	Yield	Ratio (88 : 89)
1	NO ₂	70 ^a	53:17 ^a

presence of the reacting carbonyl function as an acceptor of the vinyl radical (Figure 63). The resulting highly reactive alkoxy radical undergoes a reversible 3-*exo*-trig cyclization whose driving force is the fast β -elimination of the X[•] radical which restores a C=O function. Logically, two regioisomeric vinyl radicals can be initially formed with possible evolution for both of them, resulting generally in a mixture of **90** and **91** in ratios close to 1:1 to 1:3 with the cis form as the major product.

**Figure 63** Oxidative radical cyclizations of 5-cyclodecynone with inorganic and organic oxygen-centered radicals of type XO[•].

Finally, open-chain alkynes bearing a cyclic template could be cyclized in the presence of NO₃[•], providing annelated tetrahydrofurans derivatives such as **92** in moderate to good yields and in good diastereoselectivity (Figure 64).^{116–118}

This reactivity could be extended to annelated pyrrolidines (**93** and **94**) by introducing a pendant nitrogen arm (Figure 64).¹¹⁹ Some calculations have come to the support of all these findings.^{120–122}

It should also be mentioned that the NO₃[•] radical has been shown to oxidize aromatic amino acids such as phenylalanine and tyrosine. Two mechanisms have been proposed, which consist of hydrogen transfer or electron transfer followed by proton loss.¹²³

Figure 64 Anellated tetrahydrofurans and pyrrolidines derivatives formation.

3.3.2 Intramolecular Reactions

The work of Hartung has established the cyclization of alkoxy radicals as a very reliable method for the synthesis of tetrahydrofuran systems.^{90,91,124} This chemistry could be extended to a halocyclization process. Thus, bis-homoallylic alcohols were converted to the *N*-alkenoxythiazole-2(3*H*)-thiones or pyridine-2(1*H*)-thiones. Upon photolysis, in the presence of BrCCl_3 and either *N*- $\text{C}_4\text{F}_9\text{I}$ or diethyl 2-iodo-2-methyl malonate serving as radical trapping agents, the corresponding bromo- or iodo-tetrahydrofuran derivatives were obtained in high yields and diastereoselectivities.¹²⁵

The stereoselectivity of the 4-penten-1-oxyl radical 5-*exo*-trig cyclization has been computationally (density functional theory, DFT) addressed by Hartung, who proposed a new transition state model as an alternative to the classical Beckwith–Schiesser–Houk–Spellmeyer model.¹²⁶ More recently, the Hartung group has concentrated on cobalt-catalyzed alkenol cyclizations. Thus, bis-homoallylic alcohols were shown to undergo oxidative cyclizations upon bis{2,2,2-trifluoromethyl-1-[(1*R*, 4*S*-1,7,7-trimethyl-2-(oxo- κ O) bicyclo[2.2.1]hept-3-ylidene]ethanolato- κ O} cobalt (II) catalysis in the presence of O_2 (Figure 65).⁹⁷ Further work showed that the stereoselectivity of the (5-phenyltetrahydrofur-2-yl)alkan-1-ol formation from the corresponding pentenols was

Figure 65 Tetrahydrofuran formation using cobalt catalysis.

independent of the configuration of the alkene, confirming the initial assumption of a radical mechanism, which is depicted in Figure 65.¹²⁷

On the basis of these findings, reductive and brominative terminations of the alkenol

cyclizations were devised by the simple addition of cyclohexadiene, BrCCl₃, or DBM (Table 2 and Figure 66).

This protocol could be applied to the total synthesis of (–)-*allo*-muscaine (Figure 67) and extended to intra–inter–intra domino processes (Figure 68).^{128,129}

4 PHOSPHORUS-CENTERED RADICALS

The principal features of P-centered radicals up to 2004 have been reviewed previously.^{130,131} The present account is an update of our 2004 review. For clarity, we decided to use a similar order here.

4.1 Physical Organic Background

Several P-centered radicals and radical ions have been studied both theoretically and experimentally.

The Coote group calculated the effect of substituents on the stabilities of phosphonyl radicals and their hydroxyphosphinyl tautomers, because of the central role of the former in free-radical chemistry.¹³² It was found that the main factor for radical stabilization is the σ -effects of the substituents. The phosphorus atom is polarized with a high positive charge and is pyramidal. Thus σ -donation is stabilizing and the π -effects are minimal.

Phosphorus can go hypervalent also for radicals. Phosphoranyl radicals have been intensely studied for their properties and as intermediates of synthetic processes. Two reports illustrate this fact well.

Figure 68 Application to intra–inter–intra domino processes.

Using time-resolved kinetic studies, the Bietti group has examined the addition of alkoxy radicals to phosphites, as well as the behavior of the phosphoranyl radicals obtained.¹³³ The addition is controlled by steric factors on both the phosphite and the alkoxy radicals, while the β -scission step is controlled by the stability of the carbon radical formed.

Persilylation of the oxygen substituents in phosphoranyl radicals of the type $(\text{RO})_4\text{P}^\bullet$, where $\text{R} = \text{SiAlk}_3$, led to the first acyclic persistent P radical.¹³⁴ This opened perspectives for controlled radical polymerization and dynamic nuclear polarization.

SET from phosphines through either photosensitization or pulse radiolysis, as well as quenching of the phosphine radical cations with oxygen, has been thoroughly studied by Yasui, Majima, and others.^{135–137} Further insight was given by photoelectron spectroscopy.¹³⁸

Several new inorganic and organometallic P-centered radicals and radical ions have been prepared over the last few years. They were generally characterized by approaches employing EPR, X-ray diffraction, and modeling.

Ito and Yoshifuji reported an air-tolerant 1,3-diphosphacyclobuten-4-yl radical (**97**, Figure 69a), whose structure was solved.¹³⁹ However, in-depth EPR characterization showed that the spin was mostly away from the P atom, so **97** should be best described as a stable C-centered radical.

Insertion of metals on specific position can help stabilize new radicals. Cummins introduced resonance-stabilized monomeric P radicals (**98**, Figure 69b).¹⁴⁰ In this case, two nitridovanadiums

act as redox-active ligands, which can tune the reactivity of the complex. The latter exhibited “substantial radical character on the phosphorus atom,” which was shown experimentally by regioselective selenation and other radical reactions, all taking place at P.

Complexation by tungsten helped stabilize a triphosphaallyl radical generated from addition/rearrangement of a photogenerated $\text{P}^\bullet$ -bis-W complex to a diphosphene derivative (**99**, Figure 69c).¹⁴¹ The authors were also able to isolate the triphosphaallyl cations and anions.

Along related lines, van Gastel, Neese, and Streubel got insight into the reactivity of the P-chlorophosphanyl radical–tungsten complex (characterized by electron spin resonance ESR).¹⁴² One-electron oxidation of P-chlorophosphinoid complex of W **100** with a tritylium cation delivered the radical pair **101**, which recombined to generate a C–P bond in the transient complex **102**. Further, the reactivity of **102** depends on the substituent on phosphorous atom (Figure 69d).

The Bertrand group recently obtained the structure of a stable crystalline phosphinyl radical cation.¹⁴³ The key stabilization of the radical cation stabilization was introduced by a cationic substituent derived from a cyclic (alkyl) (amino) carbene (CAAC) (Figure 70). Radical cation **104** was obtained via one-electron oxidation of phosphalkene **103**. Compound **104** exhibits spin density mostly at the phosphorus center (0.67e), which was demonstrated experimentally via Bu_3SnH reduction to cationic phosphine **105**. Dimerization through radical recombination is prevented by the bulky and cationic substituent. P_2 Radical ions were also characterized.^{144,145}

Figure 69 Transient P-chlorophosphanyl radical complexes.

Figure 70 Synthesis of a stable phosphinyl radical cation.

4.2 Phosphorus-Based Mediators

The use of P-H compounds as radical reductants did not really catch up, and no new concept or mediator emerged during the last 6 years. Interesting applications have been reported. These are the new radical arylation of **106** to **107** as a key step leading to horsfiline (Figure 71),¹⁴⁶ cyclizations leading to medium-sized rings—for example, via 8-*endo*-trig cyclization¹⁴⁷—and intermolecular radical additions of dihaloalditol derivatives to acrylonitrile.¹⁴⁸ Both diethylphosphine oxide (DEPO) and *N*-ethylpiperidine hypophosphite (EPHP) were generally applicable.

4.3 Additions of P-Centered Radicals to Unsaturations

Several reports have focused on the addition of phosphorus radicals to unsaturated compounds, olefins, and alkynes, as well as aromatic derivatives. The addition can be the only radical event, leading to hydrophosphination or hetero-phosphination of olefins, or it can be part of a more complex process involving several unsaturations.

4.3.1 Hydrophosphination and Hetero-phosphination

Various P-H-containing derivatives could be added to olefins under radical conditions. The Parsons group reported hydrophosphination from

Figure 71 Application of P-based mediators to radical arylation.

Figure 72 Alkyne radical 1,2-thiophosphinoylation: (a) intramolecular and (b) intermolecular.

diethylthiophosphites—(RO)₂P(=S)H—¹⁴⁹ and diphenylphosphine sulfides—Ph₂P(=S)H.¹⁵⁰ Han *et al.* published the air-induced radical addition of phosphine oxides—R₂P(=O)H—and phosphinates—(RO)R'P(=O)H.¹⁵¹ The same group had previously published the AIBN-initiated addition of chiral phosphinates.¹⁵² Phosphinoyl radicals were also generated under irradiation¹⁵³ or via homolytic substitution (which also worked for phosphonyl and diaminophosphonyl radicals).^{154,155}

All the above-mentioned methods used P(V) derivatives. Trofimov reported the controlled hydrophosphanation of vinylimidazoles by secondary

phosphines.¹⁵⁶ This was initiated either by AIBN or UV irradiation and had to be carried out in the absence of air to avoid oxidation of the phosphorus atom.

The radical resulting from the addition of the initial P-centered radical could be further functionalized beyond a simple reduction. We reported the first 1,2-bis-functionalization of alkynes. Addition of the P-centered radical to the ω -functionalized alkyne **108** generated an intermediate vinyl radical (**109**), which underwent the S_H2 leading to a P,S-substituted *exo*-methylene cyclohexane (Figure 72a). The Oshima/Yorimitsu group devised

Figure 73 Preparation of bioactive bis-phosphinates via $P^\bullet$ bis-addition to an alkyne.

the intermolecular version of this process upon introducing an *S*-thiophosphinoyl xanthate (**110**), which was the source of both the P and S ends of the olefins, via a xanthate transfer reaction (Figure 72b).¹⁵⁷

Other studies on thiophosphination of terminal alkynes that delivers products with *E*-selectivity are reported using a mixture of diphenyldisulfide and diphenyldiphosphide through irradiation by a xenon lamp¹⁵⁸ with AIBN employed as initiator to activate arylthiodiphenylphosphines.¹⁵⁹

4.3.2 Hydrophosphination Step in Cascade Processes

The Parsons group has been active to extend the $P^\bullet$ addition to polyunsaturated compounds. The cascade is triggered by the initial radical C–P bond formation. This generates a carbon radical β to the phosphorus atom, which can add to suitably positioned unsaturations. This provides a synthetic route to heterocyclic Horner–Wadsworth–Emmons reagents,¹⁶⁰ as well as the cannabinoid¹⁶¹ and quinuclidine¹⁶² frameworks. This approach was also suitable for bidirectional functionalization.¹⁶³

Montchamp has reported the bis-addition of sodium hypophosphite to alkynes. Air-initiated $P^\bullet$ -radical addition takes place at the same carbon,

Figure 74 Cascade processes involving phosphonyl radicals featuring (a) a 1,5-H translocation and (b) an α -cyclopropyl radical opening.

delivering 1,1-bis-*H* phosphinates in good yields, maybe because of spontaneous precipitation of the 1,1-bis adduct.¹⁶⁴ Simple ozone oxidation delivers biologically important bis-phosphonates, such as **112** (obtained in two steps and 38% overall yield from alkyne **111**, Figure 73). Steroid conjugate **112** is a potential prodrug for delivery of the hormone to the bone for treatment of osteoporosis.

Renaud has devised a process featuring H transfer from the initially formed β -phosphonyl vinyl radical **113** and rebound cyclization to generate phosphonyl-substituted cyclopentanes (Figure 74a).¹⁶⁵

Huang and Yu reported the synthesis of dihydronaphthylphosphonates via a domino process featuring an initial addition of phosphonyl radicals onto vinylcyclopropanes such as **114**. The resulting radical **115** ring opens, thus generating a radical suited for aromatic addition to deliver the desired **116** (Figure 74b).¹⁶⁶

Figure 75 Oxidative phosphorylations (a) of heteroaryls and (b) of alkenes and alkynes.

4.3.3 Hydrophosphination Followed by Single-Electron Oxidation

Radical phosphonation of heteroaryls (Figure 75a),¹⁶⁷ as well as aryl alkenes and alkynes (Figure 75b),¹⁶⁸ can also be achieved under oxidative conditions. In these cases, radical addition is followed by single-electron oxidation of **117**, **119**, and **120** (Figure 75) to the corresponding cations (e.g., **118**, Figure 75a).

For 2-substituted thiazoles, the addition is regioselective, and leads to the α -N radical (such as

Figure 76 Key $\text{P}^*\beta$ -elimination for (a) allylations and (b) cyanations.

117, Figure 75a), possibly because it is more stabilized. In the case of aryl alkenes, the *E* diastereomers were obtained, which was explained by decreased nonbonding interactions in the intermediate radicals (such as **119**, Figure 75b). Finally, aryl alkynes deliver substituted indenones (such as **121**, Figure 75c) via a tandem addition (i) on the alkyne and (ii) on the aryl group. Rearomatization occurs after oxidation of radical **120**.

4.4 Phosphorus Radicals as Leaving Groups

4.4.1 β -Eliminations

Two new reports have used the β -elimination of P-centered radicals we uncovered in 1995,¹⁶⁹ which have been inserted into varied cascade processes.^{106, 170–172} Allyl phosphine oxides were proposed as allylating agents by Zard and coworkers via the key fragmentation of radical **121** (Figure 76a).¹⁷³ The corresponding β -phosphonyl radical was not conducive to allylation, which parallels our own observations for vinylations.

On the other hand, the phosphono-iminyl radical **122** underwent efficient fragmentation (Figure 76b).¹⁷⁴ This allowed the authors to devise a radical cyanation.

Figure 77 Radical phosphination.

4.4.2 Homolytic Substitutions

The most significant advance in synthetic phosphorus radical chemistry has been in the homolytic substitution field. Homolytic substitutions are covered in depth in another article of this encyclopedia (see **Intramolecular Homolytic Substitutions in Synthesis**), so we give only the main points of this particular reactivity here.

Ogawa introduced a photochemical variant of Yorimitsu and Oshima's¹⁷⁵ radical bisphosphination.¹⁷⁶ By replacing the alkynes with halides or xanthates, the latter authors have devised a highly elegant radical phosphination in which a P[•] is released upon substitution at P in a temporarily formed diphosphinyl derivative (Figure 77).¹⁷⁷

Coote has examined *in silico* the polymerization of strained phosphorus heterocycles. She calculated different elementary steps, involving the homolytic substitution releasing P-centered radicals, the homolytic substitution at P, as well as P[•]-releasing β -eliminations.¹⁷⁸ She concluded that radical ring-opening polymerization of small P-heterocycles should be feasible.

Studer introduced sila- and stannaphosphanes as reagents for homolytic substitutions at P.¹⁷⁹ DFT calculations indicated that the homolytic substitution likely proceeded through an associative mechanism featuring an intermediate phosphoranyl radical **123** rather than via an S_H2 pathway (Figure 78).

Studer and Curran determined the rate for the S_H involving the stannaphosphane at $\sim 9 \times 10^8 \text{ M}^{-1} \text{ s}^{-1}$.¹⁸⁰ Using the axial chirality of *o*-halo anilides, the authors reported a very nice example of chemodivergent phosphanylations of atropoisomers.

Finally, chalcogen phosphinylation of alkynes was studied by the Oshima/Yorimitsu (for sulfur¹⁵⁷) and Nomoto/Ogawa groups (for S,¹⁵⁸ Se,¹⁵⁶ and Te¹⁵⁷).

The P-chalcogen reagents needed can be prepared before the reaction,¹⁵⁷ or *in situ*.^{156–158} In the

Figure 78 Radical phosphination from sila- and stannaphosphanes.

latter case, it builds up in the initial stages of the reaction via homolytic cleavage of the S–S, Se–Se, or Te–Te bonds and, probably, homolytic substitution at P. Then bis-functionalization of the alkyne follows. Interestingly, the regioselectivity is directed by the relative rates of additions of radicals Ph₂P[•] and Ph-chalcogen[•] to the triple bond. The PhTe[•] addition rate is very slow, resulting in the preferred initial addition of the phosphinyl radicals leading to **128**, while the reverse is true for S and Se (radicals **124**, **125**, **126**, **127**). This induced a regioselectivity switch (Figure 79).

5 SULFUR-CENTERED RADICALS

The study of the properties and the reactivity of S-centered radicals (and of their relative radical ions) has attracted a vast number of research groups owing to the relevance of these species in a wide range of domains, ranging from organic synthesis to biochemistry. Intense theoretical and experimental efforts have been carried out on this subject, and we present in the next section recent advances in the field. Xanthate chemistry and homolytic substitutions are covered extensively in this encyclopedia (see **Xanthates and Related Derivatives as Radical Precursors** and **Intramolecular Homolytic Substitutions in Synthesis**), so we have included these where necessary only briefly.

5.1 Sulfur-Based Mediators

S-Centered radicals, in particular aromatic thiyl ones, represent a well-known group of radical

Figure 79 Intermolecular bis-functionalization (P-chalcogen) of alkynes and allenes. (a) Thiophosphinylation of alkynes from preformed P–S compound; (b) thiophosphinylation of alkynes from P–S derivatives obtained *in situ* through homolytic substitution; (c) selenophosphinylation of alkynes; (d) selenophosphinylation of allenes; (e) tellurophosphinylation of alkynes.

Figure 80 Thiol-mediated cleavage of allylic C–N bonds.

Figure 81 Tandem racemization–DKR of amines yielding either (*R*)- or (*S*)-enantiomers.

mediators as a result of the relative reversibility of their addition onto C–C multiple bonds. In the last decade, no new mediator has been found, although interesting applications have been reported, which will be briefly presented here. Main advances have been in the field of PRC, pioneered by Roberts.¹⁸¹ The key feature of this approach is related to the relative ease for an *electrophilic* thiyl radical to abstract hydrogen atoms to generate *nucleophilic* carbon-centered radicals.

In this context, new applications for arylthiols came from the group of Gastaldi and Bertrand, who reported the thiyl-radical-mediated cleavage of allylic C–N bonds.¹⁸² Detailed mechanistic and theoretical investigations suggested that thiyl radicals are responsible for the isomerization of the allylic amines to the enamines, which are cleaved by means of acidic work-up (Figure 80).¹⁸³

Applications were reported for the racemization of tertiary amines, either benzylic or nonactivated.^{184,185} The authors later combined an enzymatic kinetic resolution of primary amines

with a thiyl-radical-mediated racemization to obtain optically pure aliphatic amides from the corresponding racemic amines with excellent enantiomeric excess.¹⁸⁶

Further development allowed performing these racemization reactions at temperatures as low as 30 °C under near-UV irradiation instead of the traditional heating protocol, thus expanding the practical applications of the method otherwise limited by the relative thermal instability of dynamic kinetic resolution (DKR) enzymes at high temperatures. Through this approach, it has been possible to achieve either (*R*)- or (*S*)-selective DKR of chiral aliphatic amines.^{187,188} To date, this is the most efficient and mildest existing DKR of amines (Figure 81).

Through the PRC approach, benzenethiol has also been successfully employed as a catalyst for the radical reduction on aromatic azides to amines with tributylgermanium hydride.¹⁸⁹

Yamada and Tomioka used alkyl thiol PRC for the intramolecular acyl radical cyclization of alkenals.¹⁹⁰ This approach was later extended by the authors to the formal synthesis of (+)-allokainic acid and by Stoltz in its approach to (–)-cyanthiwigin F (Figure 82).^{191,192}

5.2 Addition of Sulfur-Centered Radicals onto Multiple Bonds

The most recent review on thiol-mediated radical cyclizations was published in 2008.¹⁹³ Addition of thiyl radicals to olefin can be the first step of radical-based olefin isomerizations. The β -thiyl radicals obtained from addition to a *Z* alkene undergo

Figure 82 Synthesis of natural products through thiol-mediated acyl radical cyclization.

Figure 83 Access to (–)-erythrodiene through sequential radical addition/cyclization.

β -elimination to give the less sterically congested *E* alkene after rapid rotation. This is highly relevant in several fields, first and foremost that of lipid isomerization, which has been thoroughly studied by Chatgililoglu and Ferreri,^{194–202} and is reviewed elsewhere in this encyclopedia (see **Lipid Isomerization**).

Radical addition of thiols to alkenes and alkynes is an efficient method to introduce a sulfanyl moiety onto these multiple bonds. Because of the sensitivity of radical additions to steric hindrance on the carbon undergoing addition, the reaction works generally better on terminal rather than internal alkynes. Also, alkynes are better than alkenes.

Renaud reported an efficient procedure for running cascade reactions involving 1,5-hydrogen abstraction followed by a radical cyclization in which alkenyl radicals are generated through reaction between terminal alkynes and thiophenol.^{203–205} This approach allowed an elegant synthesis of (–)-erythrodiene **131** in seven steps from cyclohexanone **129**, the key issue being represented by the control of the stereochemistry at the spiro center of **130** (Figure 83).

Renaud's group later expanded these method featuring thiol-mediated 1,5-hydrogen transfer to the

preparation of 1-azabicyclic alkanes belonging to the class of pyrrolizidines and indolizidines from *N*-substituted caprolactams.²⁰⁶

Spagnolo and Nanni studied the addition of thiyl radical on terminal alkynes tethered to thioethers and carbamothioates as a mild protocol for the tin-free generation of alkyl and acyl carbon-centered radicals (via homolytic substitution).^{189,207,208}

Alonso reported the cyclization of γ -alkynyl ketimines through addition of $\text{PhS}^\bullet$.^{209,210} Interestingly, he found that substitution of the alkyne moiety at the ε -position is crucial to determine the favored cyclization pathway. 6-Exo (resp. 5-endo) manifolds are favored with phenyl (resp. carboxymethyl) substituents.

Yorimitsu and Oshima recently reported the radical addition of thiyl radicals onto ynamides and enamides.²¹¹ A particular hydrothiolation of the former class of substrates has been achieved by Castle.²¹² Interestingly, the addition is fully regioselective, delivering the β -thioenamides, but the stereoselectivity depends on the amount of thiol used. With 1 equiv of thiol, formation of the *cis* compound was observed (reduction governed by the approach of the reductant on the kinetic product), while the *trans* adduct was obtained with excess

Figure 84 Tandem addition/cyclization and subsequent ring opening, yielding aminosugars.

thiol (thiyl-radical-mediated isomerization leads to the thermodynamic product).

Radical addition of benzenethiol on silicon-tethered vinyl groups was investigated by the group of Friestad. These radical reactions could be performed as a two-step sequence, in which $\text{PhS}^\bullet$ adds to a double bond and the resulting alkyl radical undergoes cyclization with the $\text{C}=\text{N}$ bond of an hydrazone.^{213–216} The favored anti relative configuration is consistent with a chair-like Beckwith–Houk transition state such as **132**. The resulting cyclized compounds delivered the desired products **133** after treatment with fluoride anions, which regenerated the alkene. The method was applied to the synthesis of protected amino sugars, such as L-daunosamine (**134**, Figure 84).^{217,218}

Addition of S-centered radicals on vinylidenecyclopropanes has been investigated by Shi.²¹⁹ Interestingly, the regioselectivity of the reaction could be switched completely upon changing the nature of the sulfur derivative. Diphenylphosphinodithioic acid smoothly delivered 1,2 addition products where the S atom was introduced on the cyclopropyl ring (**135**), while thioacetic acids led to addition to the central atom of the allene (**136**, Figure 85).

The group of Majumdar actively investigated radical cyclizations triggered by initial addition of $\text{PhS}^\bullet$ to alkenes and alkynes.^{220–222} It recently reported that propargylamino-substituted uracils reacted with thiophenol to yield the corresponding

Figure 85 Reversal of regioselectivity in the addition of thiyl radical on vinylidenecyclopropane.

pyrrolopyrimidines, whereas in the presence of an allyl group ortho to the propargylamino motif, 8-*endo*-trig cyclization delivered the corresponding azocines.

In most cases, sulfur radicals are generated by AIBN or Et_3B . Switching to disulfides led to alkyne and enyne hydrothiolation (**137** and **138**, respectively, Figure 86) through an amine-mediated SET process.²²³

Thiyl radical additions are uniquely suited for the 1,2 bis-functionalization of multiple bonds. Mixed thiophosphinations, thioselenations, and thiotellurations are presented in Sections 4 and 6 of this article.

Hydroxysulphenylations usually require electron-rich olefins as radical acceptors. Electron-poor olefins lead to competitive Michael additions of the nucleophilic thiols. Bachi used this reaction on substituted 1,5-dienes to access endo peroxides with promising *in vitro* antimalarial activity via a very elegant cascade (Figure 87).^{224,225} 1,2,4-Trioxanes were obtained from substituted allylic alcohols.²²⁶

An interesting exception to the electron-rich olefin rule has been reported by Naito. α,β -Unsaturated oxime ethers and hydrazones gave good yields of hydroxysulphenylated compounds **139** after reduction of the hydroperoxide (Figure 88). The preferential formation of the *trans* isomer was proposed to be due to steric effects on the radical intermediate, the C–S bond being eclipsed by the p orbital of the carbon radical.²²⁷

The authors later expanded this method to the reaction of vinylcyclopropyl oxime ethers.²²⁸ In this case, the initial thiyl radical addition is followed by

Figure 86 Amine-mediated activation of disulfides followed by addition or addition/cyclization.

Figure 87 Hydroxysulfenylation of 1,5-dienes affording endoperoxides.

ring-opening of the cyclopropyl motif. The resulting carbon-centered radical reacts with oxygen as in the previous case to deliver a linear α -hydroxyl ω -thiyl imine.

Jugé has coupled free-radical peroxy sulfidations of aryl- and alkyl-substituted olefins with a catalytic decomposition of the resulting hydroperoxide adduct (such as **141**, Figure 89) with several metal–salen complexes (**140**).²²⁹ This is a very clever way of achieving oxidative cleavage of the olefins with molecular oxygen. Evidence for a radical mechanism was deduced from the rapid isomerization of *cis*- to *trans*-stilbene before consumption of the thiol and the concomitant formation of the carbonyl derivatives.

Wille reported that thiyl radical can activate molecular oxygen, and through this approach developed a new method for the oxidative conversion of

disubstituted alkynes to α -diketones.²³⁰ Mechanistic studies indicate that this process, which proceeds without full cleavage of the alkyne bond, is initiated by intermediately formed thiylperoxyl radicals.

Wille has recently extended her examination of the self-terminating radical cyclization to thiyl radicals,²³¹ which fared poorly or not at all in that context. Thus, thiols might be useful partners for studying the crucial H-atom translocation step of the self-terminating process.

Addition onto carbon–heteroatom multiple bonds of thiyl radical has been extended to isocyanides. The group of Ogawa reported methods for the bithiolation, thiotelluration, and thioselenation of these derivatives.^{232,233} Upon visible light irradiation, very selective reactions are achieved, and the former method was applied to the synthesis of heterocycles belonging to the class of indoles (resp. quinolines) using *o*-vinyl (resp. *o*-allyl) substituted phenylisocyanides.

Figure 89 Thiyl-radical-promoted oxidative cleavage of olefins.

Manganese salts were used as catalysts for free-radical thiocyanation of indoles and anilines by Zou and Zhang.²³⁴ Ligand exchange on $\text{Mn}(\text{OAc})_3$ by a thiocyanate anion followed electron transfer to the metal-center-generated S-centered radicals, which added to electron-rich double bonds. On anilines, the reaction showed exclusive para-regioselectivity.

Wu reported manganese-catalyzed free-radical cyclizations of thioformanilides.²³⁵ Microwave irradiation was required to access the corresponding 2-substituted benzothiazoles. The synthesis of benzothiazoles (**142**) from the corresponding *N*-arylthioamides has been achieved in several other ways to exploit the reactivity of thiyl radicals. Various oxidants, such as halides,²³⁶ hypervalent iodine derivatives,^{237,238} and 2,3-dichloro-5,6-dicyanobenzoquinone (DDQ),²³⁹ have been successfully employed. A recent approach introduced a photoinduced electron transfer by chloranil.²⁴⁰ The best results were obtained with electron-rich *N*-aryl rings. Conversely, Wang has shown that the reaction of electron-poor thioamide derivatives favors dimerization to the corresponding disulfides (**143**, Figure 90).²⁴¹

Similarly, the reaction of acyl thioformanilides and activated methylene nucleophiles—such as

Figure 90 Cyclization versus dimerization upon radical activation of thioformanilides.

malononitriles or cyanoacetates—delivered penta-substituted dipyrrole disulfides.²⁴²

Naumov and Schöneich have investigated *in silico* the addition of cysteine thiyl radicals to phenylalanine (Phe) and tyrosine (Tyr).²⁴³ DFT calculations showed that this highly important bioradical may add intramolecularly to neighboring aromatic rings in Phe and Tyr, but that the π complexes are more stable in water than the fully formed cyclohexadienyl adduct radicals.

Photoinduced thiol–ene coupling is a tool widely used in polymer and bioorganic chemistry because it allows convergent coupling of two subunits via photoinduced radical hydrothiolation (see **Radical Thiol–X Click Chemistry**).^{244,245} A full review of these topics exceeds the scope of this review. Nonetheless, this approach has also been successfully applied to molecular synthesis, for example, for the synthesis of thiodisaccharides.²⁴⁶

In the context of thiyl radical reactions, xanthates and Barton's ester represent a well-known tool in synthetic organic chemistry. The former topic is examined in detail in another part of this encyclopedia (see **Xanthates and Related Derivatives as Radical Precursors**), while the latter has been highlighted in a very recent review.²⁴⁷

5.3 Elimination and Fragmentation of Sulfur-Centered Radicals and Radical Ions

Sulfur-centered radical cations can also fragment. This has been studied extensively by the Baciocchi/Lanzalunga group because of their relevance for the understanding of enzymatic redox processes. Thus, the physical organic parameters of the fragmentation of sulfide radical cations to carbocations and thiyl radicals^{248,249} as well as that of sulfoxide radical cations to carbocations and sulfinyl radicals²⁵⁰ have been determined. The latter is two orders of magnitude faster than that of the corresponding sulfides. Therefore, the general rule of reactivity that is valid for β -eliminations of β -sulfur radicals to form alkenes can be extended to radical cations, probably for the same reason (higher stability of the sulfinyl radicals).

Radiolysis-produced carbon dioxide radicals could efficiently reduce sulfonium salts through one-electron reduction in aqueous media.²⁵¹ The resulting sulfur-centered radical fragments to the most stable radical, in the reactivity order benzyl > substituted alkyl > methyl > phenyl.

Studer has reported a (moderately) atroposelective radical aryl migration involving sulfonates.²⁵² The key step in this process is a β -fragmentation of an alkoxysulfonyl radical which regenerates aromaticity.

Kampmeier and Lund have examined the regioselectivity of the bond cleavage of 9-*S*-3-sulfuranyl radicals in extraordinary depth.²⁵³ Selectivity for the fragmentation derives not only from the structure of the hypervalent radicals but also from the potential of the reductant.

Minozzi and Nanni investigated the selective C–S β -scission of thioimidoyl radicals as an effective tool for reductive defunctionalizations and intermolecular additions to electron-rich olefins.^{254,255} They propose that a sulfanyl radical—generated from a thiol and AIBN—adds to an isocyanide to yield an alkyl radical by fast β -fragmentation of the above-mentioned thioimidoyl radical **144**. This method delivers an isothiocyanide together with the desulfurated product **145** from the reacting isocyanide (Figure 91).²⁵⁶

Renaud has proposed a novel method for the efficient formation of carbon–nitrogen bonds via reaction of carbon radicals with sulfonyl azides.^{257–260} The success of the protocol—which relies on a key β -elimination of a sulfonyl radical—lies in the electrophilic character of azides (see **Unusual Radical Acceptors**). Thus, the azidonation process is particularly efficient with nucleophilic (alkyl) radicals, whereas it is slow with ambiphilic or electrophilic ones. The authors expanded these findings by coupling this process with intramolecular and intermolecular C–C bond-forming steps. They applied their method to the synthesis of several alkaloid skeletons: pyrrolidinones (**146** and **147**,²⁶¹ Hyacinthacin A₁,²⁶² and spirolactams²⁶³) (Figure 92).

Homolytic substitutions, which can be seen formally as α -elimination events, are a staple of sulfur radical chemistry. They are covered in depth in the corresponding article (see **Intramolecular**

Figure 91 C–S bond cleavage triggered by isocyanides.

Figure 92 Introduction of an azide functional group on alkyl radicals and one of its selected synthetic applications delivering pyrrolidinones.

Figure 93 Homolytic substitution at sulfur atom in the synthesis of dibenzothiophenes.

Homolytic Substitutions in Synthesis), so only a brief presentation is given here.

One of their relevant applications is the synthesis of fused aromatic polycyclic compounds. The group of Maruoka employed *o*-(*o*-iodophenyl)phenylthioethers to trigger the formation of the corresponding dibenzothiophenes (**148**, Figure 93) using BET_3 as initiator.²⁶⁴

More recently, Ila reported the synthesis of substituted benzothiophenes.²⁶⁵ We extended this reactivity to the more oxidized sulfoxides and sulfinamides.^{266,267}

6 SELENIUM-CENTERED RADICALS

Discovered in 1817, selenium has long been avoided by organic chemists owing to its high toxicity. However, for the last 50 years the element has demonstrated unexpected and multifaceted properties which have found soaring applications.^{268–271} Indeed, selenium was shown to be an essential trace element for mammalian life, and selenocystein, present in the active site of glutathione peroxidase,

was recognized as the 21st natural amino acid. In the field of radical chemistry, selenium precursors are particularly attractive as will be illustrated in this review. Radical reactions using selenium precursors have been reviewed in depth by Renaud²⁷² in 2000, so only the literature starting from this year will be covered here.

6.1 Physical Organic Background

Over the past decades, many organoselenium compounds designed to mimic the activity of selenoenzyme glutathione peroxidase (GPx) have shown promising antioxidant activities, consequently attracting the attention of the pharmaceutical industry.²⁷³ However, the exact mechanism of the redox processes involved is still unknown. Several theoretical and experimental studies on selenium radicals have been performed to make sense of the chemistry.^{274–276} The selenocysteinyl radicals were generated by laser flash photolysis, using a photolabile protecting group, and characterized by

Figure 94 Synthesis of tetrahydrofuran-3-ones by tandem radical carbonylation/cyclization.

time-resolved UV–Vis, EPR, and Fourier transform infrared spectroscopy.²⁷⁷

Using photomodulated voltammetry, Daasbjerg measured the reduction and oxidation potentials of a set of parasubstituted phenylselenanyl radicals.²⁷⁸ The values obtained were $E^{\text{ox}}_{1/2} = 0.70$ V versus saturated calomel electrode (SCE) and $E^{\text{red}}_{1/2} = -0.06$ V versus SCE for the unsubstituted phenylselenanyl radical. For the substituted compounds, both the reduction and oxidation potentials correlated linearly with the Hammett substituent coefficients.

6.2 Homolytic Substitutions at Selenium

6.2.1 Substitution by Tin- or Silicon-Centered Radicals: Phenylselenium as a Leaving Group for the Generation of Carbon-Centered Radicals

Organo selenium compounds are readily available precursors for the generation of carbon radicals. Furthermore, unlike the tin halide residues obtained from tin hydrides, the seleno-tin side products generated are usually stable on silica gel,

and easily removed from the reaction products. Carbon-centered radicals can also be generated by the homolytic cleavage of the carbon–selenium bond under irradiation,^{279,280} or by photoinduced SET.²⁸¹

The group transfer reactions of PhSe derivatives will not be detailed in this section since they are covered in another part of this Encyclopedia (see **Halogen and Chalcogen Transfer Chemistry**).

The selenium atom in phenylselenium groups can undergo homolytic substitution from tin or silyl radicals to generate alkyl radicals (even primary). In new installations, those were employed, for example, in *5-exo-trig*^{282,283} or *7-endo-trig*²⁸⁴ cyclizations. Adding a further level of complexity, Engman described a cascade where the radical **149** generated is carbonylated by carbon monoxide before the *5-exo-trig* reductive cyclization^{285,286} (Figure 94).

Alkoxy-substituted alkyl radicals were also successfully generated starting from stable O,Se-acetals. Vidal treated (phenylseleno)methyl aryl ethers with tri(trimethylsilyl)silane (TTMSS) and AIBN to form arylmethoxy radicals that added intramolecularly onto ketimines.²⁸⁷ Anomeric radicals can easily be generated by this approach.^{288–290} Thus, Shuto has reported the synthesis of β -C-glucoside **151** via the radical cyclization of silicon-tethered 1- β -phenylseleno-D-glucose derivative **150** (Figure 95).²⁹¹ Owing to the presence of bulky protecting groups, the substrate is restricted in a 4C_1 conformation. Generation of the anomeric radical through treatment with Bu_3SnH and AIBN leads to an uncommon β -selective *9-endo-trig* cyclization because of the anomeric effect. An oxidative Si–C bond fission was finally performed to obtain the desired β -C-glucoside **151** in 44% overall yield.

Figure 95 β -Selective radical C-glycosylation using a conformationally restricted 1-phenylseleno-D-xylose derivative.

Figure 96 α -Selenoester intermediate in diastereoselective tandem Mukaiyama/radical allylation.

α -Carbonyl seleno compounds have been widely used in radical synthesis because they are readily synthesized and provide a convenient access to tertiary or quaternary stereogenic centers.^{292,293} Thus, Guindon has developed a tandem Mukaiyama reaction/free-radical allylation where the intermediately formed α -selenoester **152** is reduced in the presence of allyltributyltin, Et_3B , and a Lewis acid to form stereo-defined quaternary centers via diastereoselective intermolecular radical allylation (Figure 96).^{294,295}

Unlike acyl halides, acyl selenoesters are very efficient precursors for the formation of acyl radicals. This property has been extensively exploited in the radical synthesis of polyheterocyclic compounds.²⁹⁶ It has been newly illustrated by Takahashi, who reported the 5-*exo*-trig cyclization of selenocarbonates to diastereoselectively form γ -lactones.²⁹⁷ Bennasar especially studied the generation of 2-indolylacyl radicals from the corresponding acylselenium precursors under hexabutyltin-*h* ν or Bu_3SnH -initiator conditions.^{298–301} She recently described a new route to the alkaloid isodasycarpone from the key 6-*exo*-trig cyclization of selenoester **153** (Figure 97).³⁰²

Imidoyl phenylselenanides are also efficient precursors for the generation of imidoyl radicals, as demonstrated by Bowman.³⁰³ He successfully used this approach to prepare the anticancer alkaloid Ellipticine through a radical cascade (Figure 98).³⁰⁴

Yoshimura has reported the radical synthesis of *C*-cyclonucleosides by treatment of

Figure 97 Synthesis of isodasycarpone by 6-*exo*-trig cyclization of a selenoester.

6-phenylselenouridine derivatives with TTMSS and AIBN.³⁰⁵ The reaction proceeded via a vinyl radical, which underwent hydrogen transfer and rebound cyclization.

6.2.2 Homolytic Substitution by Carbon-Centered Radicals

Diselenides possess an efficient carbon-radical capturing ability. The rate constant for the $\text{S}_{\text{H}}2$ reaction of a 5-hexenyl radical with $(\text{PhSe})_2$ was estimated to be $1.2 \times 10^7 \text{ M}^{-1} \text{ s}^{-1}$, compared to $7.6 \times 10^4 \text{ M}^{-1} \text{ s}^{-1}$ for $(\text{PhS})_2$. Ogawa beautifully exploited the differences of reactivity between disulfides and

Figure 98 Radical synthesis of Ellipticine.

Figure 99 Selective thioselenation of isocyanide **154**.

diselenides to perform the selective thioselenation of aromatic isocyanides.²³³ A mixed system of $(\text{PhS})_2$ and $(\text{PhSe})_2$ was irradiated in the presence of an isocyanide such as **154**. *In situ*-formed thiyl radical added to the isocyanide carbon, generating intermediate **155**, which was selenylated by $\text{S}_\text{H}2$ reaction from diphenylselenide. The thioselenated product **156** was carried forward to the carbacephem **157** (Figure 99). The same approach was used to perform the selenoperfluoroalkylation of acetylenes from a mixed system of perfluoroalkyl iodide and diphenyl diselenide under irradiation.³⁰⁶

Zard reported an interesting procedure in which a triphenylmethylhydrazide precursor is oxidized by phenylselenenic acid in the presence of a catalytic quantity of diphenyl diselenide.³⁰⁷ The oxidation generated diphenyldiselenide and the corresponding triphenylmethyl diazo derivative which spontaneously fragmented to deliver an acyl radical. The latter cyclized to an internal olefin to form

a carbon-centered radical which was captured by diphenyl diselenide.

Homolytic substitution at selenium is possible when the radical extruded is stabilized. Thus, ring closure of aryl radicals at selenium with extrusion of benzyl radical proceeds at a rate constant of $\sim 3 \times 10^7 \text{ s}^{-1}$ at 80°C , which is 2–4 times faster than the same reaction at sulfur.³⁰⁸ In-depth mechanistic studies were carried out by Schiesser,³⁰⁹ as well as the efficient synthesis of biologically active heterocycles.^{310–317} A recent example details the synthesis of selenochromanes via tandem intermolecular addition/intramolecular homolytic substitution at selenium.³¹⁸ Benzylic xanthates such as **158** led to the stabilized, weakly nucleophilic benzyl radical **159** under irradiation and thermal conditions. This latter added to an electron-poor olefin, and the radicals thus obtained cyclized to quantitatively deliver the six-membered selenium-containing rings (Figure 100). This reaction was also possible by

Figure 100 Tandem intermolecular addition/intramolecular homolytic substitution at selenium.

Figure 101 Formation of 2-phenylselenylated butadienes.

treatment of the reagents with triethylborane and O_2 at $0^\circ C$.

6.3 Additions of Selenium-Centered Radicals to Insaturations

Selenium radicals are more stable than their sulfur counterparts, but are less reactive toward insaturations. For example, the rate constant of addition of $PhSe^\bullet$ to vinyl monomers is 10–50-fold smaller than that of $PhS^\bullet$ to the same olefin.³¹⁹ Nevertheless, several interesting reactions triggered by intermolecular additions of $PhSe^\bullet$ to multiple bonds have been reported. Since the addition of selenium radicals is a reversible process, a radical trap must be used to pull the equilibrium.

Huang described the addition of the phenylselenium radical to methylenecyclopropane in the presence of copper acetate.³²⁰ Ring-opening of the cyclopropane led to homoallyl radical **160**, which was presumably converted to the organocopper intermediate **161**. Final β -H elimination gave

phenylselenyl-substituted buta-1,3-diene **162** (Figure 101).

Several tandem reactions initiated by addition of $PhSe^\bullet$ and terminated by S_H2 selenylations have been reported. They provide diselenated compounds that can be easily further functionalized.^{321–323} Ogawa developed a highly selective four-component coupling radical reaction of an alkyne, two differently polarized olefins, and diphenyl diselenide.³²⁴ Irradiation generated $PhSe^\bullet$, which added to the alkyne. Owing to polar effects, electrophilic vinyl radical **163** was selectively trapped by electron-rich 2-methoxypropene, affording a new nucleophilic radical **164**. Reaction of the latter with the electron-poor olefin produced 5-hexenyl radical **165**, which underwent 5-*exo*-trig ring closure. The final α -seleno radical **166** ultimately performed the S_H2 termination to give the desired product after six elementary steps (Figure 102).

$PhSe^\bullet$ can also be generated from sources other than diselenides. Yao related the 1,4-radical addition of benzeneselenenol to α,β -unsaturated ketones under (oxidizing) SET conditions (ceric(IV)

Figure 102 Four-component coupling cascade.

ammonium nitrate, CAN).³²⁵ Alternatively, Huang described the reductive formation of $\text{PhSe}^\bullet$ from *N*-(phenylseleno)phthalimide and $(\text{NH}_4)_2\text{S}_2\text{O}_8$.³²⁶

6.4 Benzeneselenenol as Radical Mediator

Benzeneselenenol is an especially fast reducing agent. Newcomb has measured that 6,6-diphenyl 5-hexenyl primary alkyl radical was trapped by PhSeH with a rate constant of $1.2 \times 10^9 \text{ M}^{-1} \text{ s}^{-1}$, close to diffusion control, compared to $1.4 \times 10^8 \text{ M}^{-1} \text{ s}^{-1}$ for PhSH and $2.4 \times 10^6 \text{ M}^{-1} \text{ s}^{-1}$ for Bu_3SnH .³²⁷

The catalysis of stannane-mediated radical chain reactions by PhSeH was introduced in 1995 by Crich and has since led to numerous synthetic applications.³²⁸ In this strategy, benzeneselenenol is generated *in situ* by reduction of diphenyl diselenide with tributyl tin hydride (1). It rapidly reduces the early radical intermediates before they can react further, which regenerates tin radicals by hydrogen abstraction. This approach is often designated as *PRC* since the polarity-mismatched reduction of the nucleophilic alkyl radical by Bu_3SnH is substituted by two polarity-matched steps involving PhSeH .

This catalysis can block radical rearrangements and other less rapid transformations, such as the

rearomatization of arenes^{329–332} or heteroaromatic rings.³³³ For example, Crich reported the reductive radical arylation of benzene as the key step for the synthesis of phenolic cyclitol derivatives. In this key step, phenolic iodide **167** was treated with Bu_3SnH , AIBN, and a catalytic amount of diphenyl diselenide. The aryl radical **168** generated added to benzene forming cyclohexadienyl radical **169**, which was trapped by benzeneselenenol and led to cyclohexadiene **170** (Figure 103).³³⁴

Schiesser reported that the yield of the hydrostannylation of a silyl enol ether increased from 20% to 95% when 10 mol% of diphenyl diselenide was added, because the reduction steps became faster than the reverse β -fragmentation of the stannyl radicals.³³⁵

Clive reported that the yield of the cyclization of alkyl radicals onto *O*-trityl oximes rose sharply in the presence of $(\text{PhSe})_2$ (Figure 104). In that case, benzeneselenenol was thought to rapidly reduce the persistent trityl radical and thus prevent the disruption of the chain propagation.³³⁶

7 CONCLUSIONS AND PERSPECTIVES

For the last five decades, radical transformations have progressively merged into the mainstream synthetic chemistry. In that evolution, radical chemistry based on the main-group elements has occupied a

Figure 103 Synthesis of a *meso*-tetraol via radical dearomatization and osmylation.

Figure 104 Effect of diphenyl diselenide on the radical closure onto *O*-trityl oximes.

prominent position. This is certainly due to the fact that main-group elements are at the origin of very unique and intriguing opportunities.

In this review, we have discussed the recent advances, over the last 10 years, in homolytic processes involving nitrogen-, oxygen-, phosphorus-, sulfur-, and selenium-centered radicals which have constituted extremely rich sources of molecular innovation. Modes of generation of these highly reactive entities, mechanistic considerations in multistep sequences, as well as stereoselectivity issues have been thoroughly addressed. Playing with heteroatoms and their connected functionalities has given rise to tremendous developments, and their

various applications in terms of substrates and finality perfectly illustrate the good health of main-group radical chemistry. Thus, just to name a few, total synthesis of natural products, glycochemistry, and even material sciences or bioorganic chemistry based on thiol–ene coupling processes, for instance, have benefited from all these advances.

A notable feature of the last decade's progress is the invention of catalytic processes to generate radical intermediates, so that, based on a variety of metal complexes or pure organic agents, very versatile transformations have been devised. It is obvious that besides the neat advantage to escape from toxic and stoichiometric mediators, catalysis constitutes a reliable entry into selectivity and, if relevant, asymmetric synthesis, by simply adjusting the electronic nature as well as the steric environment of the ligands. It is most likely the area where we can anticipate the best crop of novel findings.
